

Four-Factor Prothrombin Complex Concentrate for Urgent Reversal of Vitamin K Antagonists in Patients With Major Bleeding

Daniel J. Quinlan, MBBS; John W. Eikelboom, MBBS; Jeffrey I. Weitz, MD

Vitamin K antagonists (VKAs), such as warfarin, are widely used for prevention and treatment of arterial and venous thrombosis. Although oral or intravenous vitamin K and fresh frozen plasma are often used to reverse the anticoagulant effects of warfarin in patients who are bleeding, this approach has important limitations. Restoration of hemostasis with vitamin K relies on the hepatic synthesis of vitamin K-dependent procoagulant proteins, factors II (prothrombin), VII, IX, and X, a process that takes >6 hours. Fresh frozen plasma provides an immediate source of functional vitamin K-dependent clotting proteins, but large volumes are often required to normalize the international normalized ratio (INR). This can be problematic because it takes time to match blood type and thaw and infuse fresh frozen plasma, and the large volumes can lead to fluid overload, particularly in patients with compromised cardiac or renal function.

Article see p 1234

Prothrombin complex concentrate (PCC) provides an alternative to fresh frozen plasma for reversal of VKA-induced coagulopathy (Table). Originally developed as a source of factor IX for treatment of patients with hemophilia B, 3-factor PCC contains factors II, IX, and X but little or no factor VII. In contrast to 3-factor PCC, 4-factor PCC also contains significant amounts of factor VII. Both 3- and 4-factor PCC contain protein C and protein S, and some may also contain small amounts of heparin, which is added to prevent activation of the clotting proteins.

PCC contains the vitamin K-dependent clotting proteins in a lyophilized form and can be stored at room temperature for several years. No thawing or blood-type matching is required, and after reconstitution with a small volume of sterile water (20–40 mL), PCC can be rapidly administered without risk of fluid overload. Additional advantages of PCC over fresh frozen plasma include a negligible risk of viral transmission and transfusion-related acute lung injury.¹ Potential disadvantages

of PCC are increased cost compared with fresh frozen plasma and a small risk of thromboembolic complications.² Both plasma and PCC require coadministration of vitamin K for sustained warfarin reversal because the half-life of factor VII, a key vitamin K-dependent clotting factor, is only 6 to 8 hours, whereas warfarin has a half-life of several days.

Current guidelines recommend 4-factor PCC for situations where rapid reversal of VKA-induced coagulopathy is needed, such as in patients who require urgent surgery or in those with a life-threatening bleed.^{1,3–5} If 4-factor PCC is unavailable, 3-factor PCC can be used, and some clinicians supplement it with fresh frozen plasma or small amounts of recombinant activated factor VII (factor VIIa) as a source of factor VII. Nonactivated PCC is preferred over activated PCC, which contains factor VIIa, as well as factors II, IX and X, or recombinant factor VIIa, because there is likely to be a lower risk of thromboembolic events with nonactivated products.^{6,7} In addition, recombinant factor VIIa only replaces 1 of the 4 vitamin K-dependent procoagulant proteins.

What is the evidence supporting the use of PCC for reversal of VKA-induced coagulopathy? Two small randomized, controlled trials, which included <60 patients, suggested that PCC reverses VKA-induced coagulopathy more rapidly than vitamin K or fresh frozen plasma but were underpowered to show improvement in clinical outcomes.^{8,9} Consequently, until now, most of the evidence supporting the use of PCC for VKA reversal came from observational studies.^{2,10–13} In this issue of *Circulation*, Sarode et al¹⁴ report the results of a phase III, open-label, noninferiority, randomized, controlled trial that compared a 4-factor PCC with fresh frozen plasma for urgent reversal of VKA-associated coagulopathy in 216 patients with acute bleeding. Despite the modest sample size and the fact that the trial enrolled 69 centers in the United States and Eastern Europe, the study took >2 years to complete.¹⁵ All of the patients received intravenous vitamin K, and the doses of PCC and number of units of plasma that were infused were calculated on the basis of individual body weight and baseline INR values. More than 60% of patients presented with gastrointestinal or other sites of nonvisible bleeding, and >10% had intracranial hemorrhage. Coprimary outcomes were the effectiveness of the hemostatic response during the 24-hour period from the start of study treatment and the proportion of patients who achieved an INR value of ≤ 1.3 within 30 minutes of completion of the study infusion. Outcomes were independently adjudicated by an expert committee blinded to treatment allocation.

The median duration of PCC administration was 17 minutes compared with 148 minutes in those allocated to fresh frozen

Table. Available Treatments for Reversal of Vitamin K Antagonist–Associated Coagulopathy

Characteristic	Vitamin K	Fresh Frozen Plasma	3-Factor PCC	4-Factor PCC
Constituents	Vitamin K	All vitamin K–dependent clotting factors	Factor II, IX, X, proteins C and S*	Factor II, <u>VII</u> , IX, X, proteins C and S*
Route of administration	Oral or intravenous	Intravenous	Intravenous	Intravenous
Dose	5–10 mg	10–15 mL/kg	25–50 IU of factor IX/kg	25– <u>50 IU</u> of factor <u>IX/kg</u>
Onset of effect	6–8 h	Duration of infusion†	15–30 min†	15–30 min†
Adverse effects	Rare anaphylaxis	Fluid overload; febrile and allergic reactions; viral transmission; transfusion-related acute lung injury	Possible increase in thromboembolic complications	Possible increase in thromboembolic complications
Cost	Minimal	Moderate	High	High
Other	Intravenous administration produces more rapid reversal	Requires coadministration of vitamin K to sustain reversal	Requires coadministration of vitamin K to sustain reversal; may require coadministration of plasma or recombinant factor VIIa as a source of factor VII	Requires <u>coadministration of vitamin K to sustain reversal</u>

PCC indicates prothrombin complex concentrate.

*Some preparations also contain antithrombin and small amounts of heparin.

†Onset can also be affected by the dose administered.

plasma, and corresponding infusion volumes were 99.4 and 813.5 mL, respectively. The proportion of patients achieving effective hemostasis within 24 hours was similar in the 2 treatment groups (72.4% versus 65.4%; noninferiority $P=0.0045$). The proportion of patients in the PCC group who achieved an INR ≤ 1.3 within 30 minutes of the end of infusion was 62.2%, which was lower than the 93.0% observed in a previous observational study using the same PCC protocol¹¹ but still substantially higher than the 9.6% in the plasma group; a difference that remained evident at 24 hours. Among the subgroup of patients with visible or musculoskeletal bleeding, 82.6% of those given PCC achieved effective hemostasis at 4 hours compared with 50.0% in the plasma group ($P=0.02$). The safety profiles of PCC and fresh frozen plasma were comparable, as were the rates of thromboembolic events (7.8% and 6.4%, respectively), mean number of units of packed red blood cells transfused (1.4 and 1.2, respectively), and the median length of hospital stay. Patients in the PCC group had a lower rate of treatment-related adverse events than those given plasma (9.7% and 21.1%, respectively). There were 10 deaths in the PCC group and 5 in the group given fresh frozen plasma, but only 1 death was deemed to be treatment related.

What are the implications of the study by Sarode et al¹⁴ for clinical practice? First, the finding of more rapid reversal of the INR with a 4-factor PCC than with plasma provides additional support for the guideline that gives preference to PCC over fresh frozen plasma for patients who require urgent reversal of VKA-associated coagulopathy.^{1,3–5} Although the more rapid anticoagulation reversal achieved with a 4-factor PCC did not translate into more effective hemostasis at 24 hours or to an overall improvement in clinical outcomes, hemostatic improvement in the subgroup of patients with musculoskeletal or overt bleeding and a lower incidence of fluid overload support this conclusion. In line with this recommendation, the US Food and Drug Agency licensed Kcentra (CSL Behring), the 4-factor PCC that was used in the study by Sarode et al¹⁴ for urgent reversal of warfarin-associated coagulopathy in patients with acute major bleeding.¹⁶

Second, the 7% to 8% overall rate of thromboembolic events and the 3% to 4% rate of treatment-related thromboembolism reported in this study underscore the importance of appropriate use of PCC in patients with VKA-associated coagulopathy. Although direct evidence that PCC or fresh frozen plasma causes thrombosis is lacking, there is substantial evidence that reversal of antithrombotic therapy in patients at risk is associated with an increase in thromboembolic events. Consequently, it seems prudent to restrict the use of PCC or fresh frozen plasma to patients with major or life-threatening bleeding or to those requiring urgent surgery.

What are the unresolved issues? First, the optimal PCC dose for reversal of VKA-associated coagulopathy remains uncertain.¹⁷ Although Sarode et al¹⁴ administered 4-factor PCC at doses of 25 to 50 IU of factor IX per kilogram of body weight, 30 minutes after drug infusion, 37.8% of the patients still had INR values >1.3 . It is uncertain whether higher doses of PCC would have resulted in INR correction in a greater proportion of patients. The results of 2 recently completed but as yet unpublished trials comparing 4-factor PCC with plasma for reversal of VKA-associated coagulopathy in patients requiring urgent surgery or invasive procedures (Clinical Trial Registration NCT00618098 and NCT00803101) may help to clarify this issue.

Second, we still need to know whether PCC improves clinical outcomes in patients with VKA-associated coagulopathy who present with serious bleeding. The currently available data are restricted to observational studies, which are subject to confounding and do not provide reliable evidence of efficacy or safety, and to small randomized trials.

The study by Sarode et al¹⁴ has important implications for future research. The introduction of several new oral anti-coagulants as alternatives to VKAs has focused attention on the need for effective reversal agents to manage patients with major bleeding or those who require urgent surgery or intervention. Specific antidotes have been developed for both dabigatran and oral factor Xa inhibitors, but their efficacy and safety have yet to be demonstrated.^{18,19} Trials of reversal agents

in patients with serious bleeding are challenging because consent can be difficult to obtain in the requisite time frame in such patients, a factor that likely contributed to the slow recruitment in the study by Sarode et al.¹⁴ Ideally, studies with reversal agents should not only determine whether treatment results in more rapid normalization of tests of coagulation but also should evaluate whether this, in turn, improves clinical outcomes. Large clinical trials are needed to show improvements in clinical outcomes. We have yet to see such trials in patients with VKA-associated bleeding, and we are even less likely to see them in patients taking the new oral anticoagulants, because these agents are associated with less bleeding, particularly intracranial bleeding, than warfarin.

In conclusion, the study by Sarode et al¹⁴ is the first rigorously designed, carefully conducted, randomized, controlled trial to show that 4-factor PCC provides more rapid normalization of the INR than fresh frozen plasma in warfarin-treated patients who present with acute bleeding. In addition, the study shows an improvement in hemostasis with PCC in a subset of such patients. These results provide further support for current guidelines that give preference to 4-factor PCC over fresh frozen plasma for the management of VKA-associated coagulopathy in patients who present with major or life-threatening bleeding. This trial also provides a framework for the future evaluation of reversal agents in patients treated with new oral anticoagulants.

Efficacy and Safety of a 4-Factor Prothrombin Complex Concentrate in Patients on Vitamin K Antagonists Presenting With Major Bleeding

A Randomized, Plasma-Controlled, Phase IIIb Study

Ravi Sarode, MD; Truman J. Milling Jr, MD; Majed A. Refaai, MD;
Antoinette Mangione, MD, PharmD; Astrid Schneider, PhD; Billie L. Durn, BS;
Joshua N. Goldstein, MD, PhD

Background—Patients experiencing major bleeding while taking vitamin K antagonists require rapid vitamin K antagonist reversal. We performed a prospective clinical trial to compare nonactivated 4-factor prothrombin complex concentrate (4F-PCC) with plasma for urgent vitamin K antagonist reversal.

Methods and Results—In this phase IIIb, multicenter, open-label, noninferiority trial, nonsurgical patients were randomized to 4F-PCC (containing coagulation factors II, VII, IX, and X and proteins C and S) or plasma. Primary analyses examined whether 4F-PCC was noninferior to plasma for the coprimary end points of 24-hour hemostatic efficacy from start of infusion and international normalized ratio correction (≤ 1.3) at 0.5 hour after end of infusion. The intention-to-treat efficacy population comprised 202 patients (4F-PCC, $n=98$; plasma, $n=104$). Median (range) baseline international normalized ratio was 3.90 (1.8–20.0) for the 4F-PCC group and 3.60 (1.9–38.9) for the plasma group. Effective hemostasis was achieved in 72.4% of patients receiving 4F-PCC versus 65.4% receiving plasma, demonstrating noninferiority (difference, 7.1% [95% confidence interval, -5.8 to 19.9]). Rapid international normalized ratio reduction was achieved in 62.2% of patients receiving 4F-PCC versus 9.6% receiving plasma, demonstrating 4F-PCC superiority (difference, 52.6% [95% confidence interval, 39.4 to 65.9]). Assessed coagulation factors were higher in the 4F-PCC group than in the plasma group from 0.5 to 3 hours after infusion start ($P<0.02$). The safety profile (adverse events, serious adverse events, thromboembolic events, and deaths) was similar between groups; 66 of 103 (4F-PCC group) and 71 of 109 (plasma group) patients experienced ≥ 1 adverse event.

Conclusions—4F-PCC is an effective alternative to plasma for urgent reversal of vitamin K antagonist therapy in major bleeding events, as demonstrated by clinical assessments of bleeding and laboratory measurements of international normalized ratio and factor levels.

Clinical Trial Registration—URL: <http://www.clinicaltrials.gov>. Unique identifier: NCT00708435.

Key Words: anticoagulants ■ hemorrhage ■ plasma ■ prothrombin complex concentrates ■ vitamin K antagonist

Vitamin K antagonists (VKAs) are prescribed routinely for the treatment and prevention of thromboembolic events, with >22 million prescriptions issued for warfarin in the United States annually.¹

Editorial see p 1179 Clinical Perspective on p 1243

In clinical practice in the United States, major hemorrhage in VKA-treated patients reportedly occurs at an annual rate of

1.7% to 3.4%.² Furthermore, there are >60 000 annual emergency department visits for hemorrhagic complications in VKA-treated patients.³ Bleeding and supratherapeutic international normalized ratio (INR) are also common manifestations of adverse drug events in older adults, accounting for ≈ 42 000 hospitalizations annually in the United States.⁴ Patients presenting with acute hemorrhage require rapid VKA reversal via prompt restoration of vitamin K–dependent coagulation factors

(VKDFs).⁵ The first step is the administration of vitamin K; however, reversal can take several hours, and therefore it is not recommended as monotherapy for acute bleeding.^{5,6}

VKDF replacement can be achieved by administering plasma or prothrombin complex concentrate (PCC).⁷⁻⁹ Despite widespread use, the efficacy of plasma for urgent VKA reversal has not been established, and it has several drawbacks, including (1) time delays for ABO blood typing and thawing of frozen plasma; (2) large volumes and long infusion times to reach the factor levels necessary to correct coagulopathy; (3) risk of pathogen transmission; and (4) risk of transfusion-related acute lung injury and transfusion-associated circulatory overload, which are leading causes of transfusion-related deaths.⁷⁻¹⁰

An alternative to plasma is PCC. There are 2 types of PCCs: activated (licensed for treatment of hemophilia A or B with an inhibitor) and nonactivated. Nonactivated PCCs are lyophilized concentrates of VKDFs, referred to as 3-factor (contain significant quantities of factors II, IX, and X) or 4-factor (4F; also contain sufficient factor VII).^{7,11} PCCs can be administered promptly because of their relatively small infusion volume and because there is no need for thawing or blood-type matching.⁷ PCCs are effective for urgent VKA reversal¹² and are considered preferable to plasma for rapid INR correction in many countries,^{7,13} which is highlighted in treatment guidelines from a number of organizations, including the American College of Chest Physicians, the British Committee for Standards in Haematology, and the Task Force for Advanced Bleeding Care in Trauma.^{5,6,14}

This prospective, randomized, multinational clinical trial compared 4F-PCC with plasma for urgent VKA reversal in patients with acute major bleeding.

Methods

Study Design

This prospective, randomized, open-label, active-controlled, noninferiority phase IIIb trial was conducted at 36 sites across the United States and Europe. The study was sponsored by CSL Behring, registered at <http://www.clinicaltrials.gov/ct2/show/NCT00708435>, and performed in accordance with local ethics regulations; written informed consent was obtained from all patients.

Patients were randomly assigned (1:1) to receive either 4F-PCC (Beriplex P/N, CSL Behring, Marburg, Germany) or plasma. Patients were assigned by a centrally managed biased-coin minimization method,¹⁵ which controlled for balance in number of patients among treatment arms overall and per site as well as among bleeding type (comprising gastrointestinal, visible, intracranial hemorrhage, musculoskeletal, and other nonvisible bleeding). Study staff were not blinded to treatment allocation because of the inherent characteristics of the study drugs. Therefore, hemostatic efficacy was assessed by a blinded, independent Endpoint Adjudication Board (EAB). An independent Data Safety Monitoring Board reviewed unblinded data to assess patient safety. Serious adverse events (AEs) of interest to the Data Safety Monitoring Board (thromboembolic events, deaths, late bleeding events) were reviewed by a blinded, independent Safety Adjudication Board (SAB). Further details are in Table I in the online-only Data Supplement.

Efficacy End Points

Because of the complexity of assessing VKA reversal in a population experiencing diverse types of bleeding, the study was designed with 2 complementary coprimary end points. One coprimary study end point

was hemostatic efficacy of the intervention (4F-PCC or plasma), assessed over a 24-hour period from the start of infusion. The other coprimary end point was rapid INR reduction (≤ 1.3) at 0.5 hour after the end of infusion. Secondary efficacy end points included plasma levels of VKDFs (factors II, VII, IX, and X) and natural anticoagulant proteins (proteins C and S) and time to INR correction (a complete list appears in Table II in the online-only Data Supplement).

Patients

Patients (≥ 18 years of age) receiving VKA therapy with an elevated INR (≥ 2.0 within 3 hours before study treatment) and experiencing an acute major bleeding event were eligible. Acute major bleeding was defined as 1 of the following: life-threatening or potentially life-threatening (according to the treating physician); acute bleeding associated with a fall in hemoglobin ≥ 2 g/dL; and bleeding requiring blood product transfusion. Exclusion criteria are listed in Table 1.

Treatment

On day 1, each patient received his or her assigned study treatment according to baseline INR and body weight (Table 2).¹⁶ 4F-PCC was administered as a single intravenous dose, with a maximum infusion

Table 1. Exclusion Criteria

- Expected survival of < 3 d or expected surgery* in < 1 d
- Acute trauma for which reversal of vitamin K antagonists alone would not be expected to control or resolve the acute bleeding event
- Use of unfractionated or low-molecular-weight heparin < 24 h before enrollment or expected need < 24 h after start of infusion†
- History of thrombotic event, myocardial infarction, disseminated intravascular coagulation, cerebral vascular accident, transient ischemic attack, unstable angina pectoris, severe peripheral vascular disease at ≤ 3 mo of enrollment
- Known history of antiphospholipid antibody syndrome
- Suspected/confirmed sepsis at enrollment
- Administration of plasma, plasma fractions, or platelets ≤ 2 wk before study (administration of packed red blood cells permitted)
- Large blood vessel rupture (eg, aortic dissection or ruptured aortic aneurysm)
- Preexisting progressive fatal disease with a life expectancy of < 2 mo
- Known inhibitors to factors II, VII, IX, or X; or hereditary protein C or S deficiency; or heparin-induced, type II thrombocytopenia
- Treatment with any other investigational medicinal product ≤ 30 d before study
- Presence or history of hypersensitivity to components of the study medication
- Patients with intracranial hemorrhage:
 - Glasgow Coma Scale score < 7 ‡
 - Intracerebral hematoma volume > 30 cm³ (assessed by ABC/2 formula)
 - For subdural hematomas: maximum thickness ≥ 10 mm, midline shift ≥ 5 mm
 - For subarachnoid hemorrhage: any evidence of hydrocephalus
 - Infratentorial intracranial hemorrhage location
 - Epidural hematomas
 - Intraventricular extension of hemorrhage
 - Modified Rankin Scale score > 3 before intracranial hemorrhage

*Patients with acute major bleeding requiring minimally invasive procedures (eg, endoscopy, bronchoscopy, central lines) that were indicated for diagnostic or therapeutic reasons were not excluded per protocol, as long as plasma was intended to be given for treatment of major bleeding.

†Exclusion added at time of amendment.

‡Modified from Glasgow Coma Scale score < 9 to Glasgow Coma Scale score < 7 on request of Food and Drug Administration.

Table 2. Dose of Study Treatment per Baseline INR

Baseline INR	4F-PCC Dose, IU of Factor IX per kg Body Weight*	Plasma Dose, mL per kg Body Weight*
2 to <4	25	10
4–6	35	12
>6	50	15

4F-PCC indicates 4-factor prothrombin complex concentrate; and INR, international normalized ratio.

*Dose calculation based on 100 kg body weight for patients weighing >100 kg. Maximum dose ≤5000 IU of factor IX (4F-PCC) or ≤1500 mL (plasma).

rate of 3 IU/kg per minute. The quantity (IU) of active ingredients per vial of 4F-PCC was approximately as follows: factor II, 380 to 800; factor VII, 200 to 500; factor IX, 400 to 620; factor X, 500 to 1020; protein C, 420 to 820; and protein S, 240 to 680. Plasma was infused intravenously with a study protocol–recommended rate of 1 U per 30-minute interval.

All patients were to receive vitamin K by slow intravenous infusion dosed according to 2008 American College of Chest Physicians guidelines (5–10 mg)¹⁷ or local clinical practice if different.

Assessments

Traditional trials for evaluating coagulation factor products (eg, hemophilia treatments) are single-arm designs with subjective hemostasis end points.^{18–20} To reduce potential investigator bias and to increase end point objectivity, a hemostatic efficacy scale was developed in discussion with the Food and Drug Administration for adjudication by a blinded EAB. Hemostatic efficacy was rated by the EAB as excellent, good, or poor/none. Effective hemostasis was defined as a rating of excellent or good over a 24-hour period from the start of infusion; noneffective was defined as a rating of poor/none. Data provided to the EAB for assessment included hemoglobin, hematocrit, any additional hemostatic treatments, AE data, and clinical outcome over the 24-hour assessment period. Objective pre-defined hemostasis criteria specific to each category of bleeding were used (Table III in the online-only Data Supplement). Patients were assigned a poor/none hemostatic efficacy rating if their management required administration of any hemostatic products other than study product or packed red blood cells within 24 hours after the start of study product infusion.

At the request of the Food and Drug Administration, the time points used for assessment of the primary rating of hemostatic efficacy for patients with musculoskeletal or visible bleeding were modified (from 3 and 6 hours after the start of infusion to 1 and 4 hours after the end of infusion) during the study. Consent was reobtained from the majority of affected patients before the assessment of hemostatic efficacy. Two patients were assessed with the use of the preamendment time points and therefore had missing data for the hemostatic efficacy end point. These patients were excluded from the intention-to-treat (ITT) efficacy (ITT-E) and per protocol analyses.

The total volume and total infusion time of each study treatment were recorded. Blood samples were drawn for determination of INR and levels of VKDFs, protein C, and protein S before study product infusion and 0.5, 1, 3, 6, 12, and 24 hours after start of infusion, as well as for determination of INR at 0.5 hour after end of infusion. Additional hematology parameters (hemoglobin and platelet count) were measured before infusion and 3 and 6 hours after start of infusion.

Baseline INR was assessed ≤3 hours before start of infusion. AEs and serious AEs were recorded by study investigators. AEs and concomitant medications were recorded at every time point up to day 10 (visit window days 7–11); serious AEs were recorded up to day 45 (visit window days 43–51).

Statistical Analysis

Data were analyzed with the use of SAS (SAS Institute Inc) version 9.1.3 and version 9.2. Sample size was based on assumptions

of effective hemostasis for 85% in patients in the plasma group and 90% in the 4F-PCC group. It was originally estimated that (including a 10% dropout rate) 92 patients per group (total=184) would yield 84% power to show noninferiority of 4F-PCC versus plasma. The significance level used for the power calculation of hemostatic efficacy was 1-sided 0.025. After the protocol amendment to the hemostatic efficacy end point, target enrollment was increased to 212 to preserve study power. No power calculation was made for the INR end point measured at 0.5 hour after end of infusion.

Noninferiority analyses were conducted on the ITT-E population via calculation of the 2-sided 95% confidence interval (CI) for the difference in the proportions of patients with effective hemostasis and separately for the coprimary end point of INR reduction in the 2 treatment groups (4F-PCC minus plasma) according to the method of Farrington–Manning.²¹ Noninferiority of 4F-PCC was demonstrated if the lower limit of the 95% CI for the between-group difference was greater than –10%. 4F-PCC would be successfully claimed noninferior to plasma if noninferiority was shown for both the hemostatic efficacy and INR reduction end points. If noninferiority was shown, there would be an additional test for superiority of the effect of 4F-PCC compared with that of plasma for each of the coprimary end points. Superiority for an end point would be declared if the lower bound of the 95% CI exceeded zero. No adjustment to the type I error was required for this closed test procedure after the establishment of noninferiority.

The ITT population comprised all patients randomized to a treatment group. The ITT safety (ITT-S) population comprised all patients from the ITT population who had received any portion of study product. The ITT-E population comprised all patients from the ITT population who had received any portion of study product, who presented with acute major bleeding, and who had an INR >1.3 before infusion with study product. The per protocol population comprised all patients from the ITT-E population, excluding those with major protocol deviations. Patients with missing data for the hemostatic efficacy assessment were scored as noneffective for the ITT and ITT-E analyses and excluded from the per protocol analysis; if the INR measurement at 0.5 hour after infusion was missing, the patient was counted as having no rapid INR reduction for the ITT-E analysis.

Analyses of secondary end points were considered supportive, and no corrections for multiple comparisons were performed. A secondary analysis of the hemostatic efficacy end point was performed with the use of the original rating categories. Each category was compared between treatments with a Cochran–Mantel–Haenszel test. VKDF/protein levels were analyzed at each time point with a 2-tailed Wilcoxon rank sum test for between-group comparisons and a signed rank test for within-group changes from baseline. Time to INR correction data was summarized per treatment group in life tables and respective survival time graphs. Missing event time data or patients without events were censored at the longest nonmissing time. Between-group comparisons of INR per time point were analyzed by the 2-tailed Wilcoxon rank sum test. Safety data were analyzed descriptively.

Results

Demographics and Treatment

Two hundred sixteen patients were randomized; 103 patients received 4F-PCC, and 109 received plasma (Figure 1). The proportions of patients meeting the acute major bleeding criteria are detailed in Table IV in the online-only Data Supplement. The ITT-E population comprised 202 patients (4F-PCC, n=98; plasma, n=104); reasons for loss and exclusion are in Figure 1. Baseline data and characteristics were similar between groups (Table 3).

Infusion durations, volumes, and rates reflected the different study substances involved (Table 4).

Four patients in the 4F-PCC group and 2 in the plasma group did not receive vitamin K during the study. Eight patients in

the 4F-PCC group and 3 in the plasma group received vitamin K by a nonintravenous route. The timing of vitamin K therapy in relation to study product infusion was comparable between groups (data not shown).

Most hematology variables were within the same ranges at baseline in both groups (data not shown). There was no difference between groups in the mean number of packed red blood cell units transfused in the 24 hours after the start of infusion (Table 4). Lengths of hospital stays were similar between groups (Table V in the online-only Data Supplement).

Efficacy

Hemostatic Efficacy

Effective hemostasis (efficacy rating excellent or good) was achieved in 71 patients (72.4%) in the 4F-PCC group versus 68 (65.4%) in the plasma group (Table 5). Analysis of the group difference confirmed the noninferiority of 4F-PCC to plasma according to the predefined criterion (difference, 7.1% [−5.8 to 19.9]). The treatment difference did not demonstrate superiority.

There was no difference between groups in the number of patients with an excellent hemostatic efficacy rating at 24 hours ($P=0.50$). A subanalysis stratified by type of bleed did not reveal statistically significant differences between interventions for any category of bleed (Table VI in the online-only

Data Supplement). However, visible and musculoskeletal bleeding could be assessed earlier than other bleeding types (at 4 hours compared with 24 hours). In a post hoc analysis, significantly more patients had effective hemostasis in the 4F-PCC group than the plasma group when visible and musculoskeletal bleeding (rated at 4 hours) were analyzed ($P=0.0200$; Table 6).

INR Correction

Rapid INR reduction (INR ≤ 1.3 at 0.5 hour after the end of infusion) was achieved in 61 patients (62.2% [95% CI, 52.6 to 71.8]) in the 4F-PCC group versus only 10 (9.6% [95% CI, 3.9 to 15.3]) in the plasma group (Table 7). Analysis of the group difference demonstrated superiority of 4F-PCC over plasma (difference, 52.6% [39.4 to 65.9]).

Patients in the 4F-PCC group achieved INR correction more rapidly than those in the plasma group; 1 hour after the start of infusion, 68 patients (69%) in the 4F-PCC group had an INR ≤ 1.3 compared with none in the plasma group. This trend continued at the subsequent time points and was still evident at 24 hours after start of infusion (88% versus 58%, respectively; Figure 2A). Furthermore, median INR was significantly lower in the 4F-PCC group compared with the plasma group until 12 hours after the start of infusion (Figure 2B).

In a post hoc analysis, the 97.5% Farrington–Manning risk difference CIs for hemostatic efficacy and rapid INR reduction

were also calculated with the assumption that the noninferiority boundary was –10%. These 97.5% CIs are equivalent to testing each of the 2 end points at individual 1-sided levels of $\alpha=0.0125$. In this way, the multiplicity of testing for superiority in 2 coprimary end points was addressed with preservation of the type I error of a 0.025 significance level. For hemostatic efficacy, the 97.5% CI was –7.6% to 21.7%. For rapid INR reduction, the 97.5% CI was 37.5% to 67.7%. The lower bound of this CI is greater than zero, and therefore superiority can be declared for 4F-PCC for the rapid INR reduction end point.

Coagulation Factor/Protein Levels

Mean preinfusion levels of VKDFs, protein C, and protein S were similar between groups ($P>0.05$). Figure 3 shows changes in factor levels over time. Mean factor levels were significantly higher in the 4F-PCC group than the plasma

group at 0.5, 1, 3, and 6 hours ($P < 0.05$) apart from factor VII at 6 hours (not significantly different between groups; $P = 0.19$).

Results were similar for the coprimary end points when analyzed by country/region (Tables VII and VIII in the online-only Data Supplement). Similar results were also seen for the ITT (Tables IX and X in the online-only Data Supplement) and per protocol populations (data not shown).

Safety

Safety outcomes were assessed with the use of the ITT-S population (Figure 1). There were 66 of 103 patients in the 4F-PCC group and 71 of 109 patients in the plasma group with ≥ 1 AE (Table 8). AEs considered by investigators to be treatment related were reported for 10 patients in the 4F-PCC group and 23 in the plasma group. Serious AEs were reported for 32 patients in the 4F-PCC group and 26 in the plasma group, of which 2 (ischemic stroke, deep vein thrombosis in the 4F-PCC group) and 4 (myocardial ischemia [$n = 2$], respiratory failure, fluid overload in the plasma group) were considered treatment related by investigators (Table XI in the online-only Data Supplement).

Thromboembolic AEs were reported during the study for 8 patients in the 4F-PCC group and 7 in the plasma group (Table 8). Four patients in the 4F-PCC group and 3 patients in the plasma group had events considered treatment related by investigators. There were 5 patients in the 4F-PCC group and 3 patients in the plasma group with serious thromboembolic events, which were reviewed by the SAB. The SAB adjudicated that 2 patients in the 4F-PCC group and 2 in the plasma group had serious thromboembolic events that were treatment related. The SAB did not confirm 1 investigator-listed serious AE of myocardial infarction (4F-PCC group) as a thromboembolic event.

Five patients (4.9%) in the 4F-PCC group had fluid overload or similar cardiac events (Table 8 and Table XII in the online-only Data Supplement; preferred terms: fluid overload, pulmonary edema, cardiac failure congestive, cardiac failure chronic, and cardiac failure), and none were considered treatment related by investigators. Fourteen patients (12.8%) had fluid overload or similar cardiac events after administration of plasma, and 7 were considered treatment related by investigators.

By day 30 after infusion, there were 6 deaths in the 4F-PCC group and 5 in the plasma group, of which 1 (sudden death after hospital discharge, 7 days after receiving 4F-PCC, cause unknown) was considered by the SAB (but not by the investigator) to be treatment related. Four additional deaths occurred in the 4F-PCC group between days 30 and 45; no additional deaths were recorded for the plasma group. Deaths are detailed in Table XIII in the online-only Data Supplement. Notably, 8 of 10 patients in the 4F-PCC group and 4 of 5 patients in the plasma group died after being placed on comfort care.

Discussion

This was the first randomized clinical trial to compare 4F-PCC and plasma for urgent VKA reversal in patients with major bleeding. The study met the coprimary end points: 4F-PCC was noninferior to plasma for hemostatic efficacy and for rapid INR reduction. Consistent with the rapid reduction in INR, mean plasma levels of VKDFs markedly increased to

Table 6. Hemostatic Efficacy by Time of Rating (Post Hoc Analysis; Intention-to-Treat Efficacy Population)

	Treatment Group		Difference 4F-PCC Minus Plasma, % (95% CI)*
	4F-PCC (n=98)	Plasma (n=104)

*95% CI and P value based on a Wald test with continuity correction.

$>60\%$ at 0.5 hour after the start of 4F-PCC infusion, whereas increases in factor levels after administration of plasma were significantly slower. Between 3 and 24 hours (when vitamin K begins to take effect), factor levels in the plasma group trended toward those seen in the 4F-PCC group.

The rapid INR reduction and factor level increments are consistent with other studies demonstrating that PCCs are a clinically useful means to rapidly replace VKDFs and effectively lower INR.^{16,22-25} A number of hypotheses might explain why this 4F-PCC achieved superiority to plasma for rapid INR reduction and achieved noninferiority to plasma for hemostatic efficacy. Although it is possible that patients with less severe coagulopathies (INR 2-4) benefited from supportive measures aimed at stopping bleeding, there was no evidence of a difference in hemostatic efficacy between 4F-PCC and plasma for each baseline INR group. The hemostatic efficacy rating might have been higher for the 4F-PCC group if only patients with severe bleeding were included. However, it would not have been practical or feasible to enroll enough patients if the stringency of the entry criteria was increased. The clinical hemostasis assessments used data collected throughout the 24-hour period after study product administration; this timing might have limited our ability to detect differences. Because of the

*Defined in Table XIV in the online-only Data Supplement.

†Defined as events for which there was a relationship to study treatment in the opinion of the investigator. AEs with missing relationship were considered treatment related.

‡As assessed by the Safety Adjudication Board; no deaths in either group were classified as related by an investigator.

there was a more pronounced clinical effect of 4F-PCC compared with plasma (Table 6).

Historically, clinical trials of hemostasis have had limitations, some of which were present in this trial. Commonly, trials with bleeding end points lack defined efficacy criteria or defined time points for analysis, and most hemostatic efficacy scales have some subjective elements. In this trial, end points consistent with standard clinical assessments and time points were explicitly defined for the blinded EAB. This was the first clinical trial to use an EAB for this indication, which may explain why the frequency of hemostatic efficacy in this trial was different than anticipated on the basis of other studies in which nonstandardized assessments were used. Another challenge in clinical bleeding trials is the inability to perform direct assessments of hemostasis (continuously and in real time) for many types of bleeding, such as gastrointestinal hemorrhage. The timed nature of the assessments in this trial meant that actual hemostasis may have been achieved earlier than recorded.

The importance of the timing of assessments can also be seen for the rapid INR reversal (INR \leq 1.3) end point. This end point, measured from the end of the infusion, did not capture key differences between the 2 treatments: preparation and administration time. The median infusion time was >8 times longer in the plasma group than the 4F-PCC group. Therefore, there was a substantial difference between initiation of treatment and the assessment time point. In a clinical context, within 1 hour of the start of infusion, more than two thirds of patients had INR \leq 1.3 in the 4F-PCC group compared with none in the plasma group.

This study was not powered to demonstrate significant differences between groups for safety outcomes. Overall, the AEs observed in the 4F-PCC and plasma groups were consistent with their respective safety profiles and this population with multiple comorbidities. The SAB reviewed all study deaths and adjudicated that 1 death (patient died at home with unknown cause 7 days after administration of 4F-PCC) was related to study product. There was no unifying pattern to the deaths except for the frequent finding of a high comorbid burden, advanced age, and death after being placed on comfort care (12 of 15 patients).

Historically, the association of PCCs with thromboembolic events has been a concern. Two recent comprehensive reviews, based on single-arm studies of PCCs, concluded that there is a low risk of thromboembolic events in patients treated with PCCs for VKA reversal and that underlying disease and dosing may be important factors in increasing risk.^{13,26} This study found no evidence of an increased thromboembolic risk associated with this 4F-PCC compared with plasma; thromboembolism might occur in this patient population because of underlying risks irrespective of the means used to reverse VKA.^{27,28}

Fluid overload and similar cardiac events occurred relatively frequently after plasma transfusion for VKA reversal, as described previously.^{7,29} PCCs have several safety advantages compared with plasma with respect to rare but important AEs, many of which are not measurable in a trial such as this. Plasma transfusions are associated with allergic reactions, risk of transfusion-associated circulatory overload, transfusion-related acute lung injury, and pathogen transmission³⁰⁻³⁴; however, several strategies have reduced many of these risks.³³ This study was not powered to assess the incidence of transfusion-related acute lung injury, and therefore specific data are not available. PCCs undergo a series of pathogen-reduction and -inactivation steps and are associated with a minimal risk of pathogen transmission.^{13,26} The low infusion volume of PCCs avoids transfusion-associated circulatory overload; the median volume of plasma administered in this study was >8 times greater than the volume of 4F-PCC (813.5 versus 99.4 mL).

Overall, these results add to the existing evidence that 4F-PCC is an acceptable alternative to plasma for VKA reversal in time- and volume-critical situations. PCCs normalize the INR more rapidly than plasma,³⁵⁻³⁸ which has led to their widespread use for VKA reversal throughout Europe for >20 years.^{12,39} This preference for PCCs over plasma is reflected in many guidelines for VKA reversal.^{5,6,14}

Conclusions

This was the first randomized, controlled study comparing PCC with plasma in patients receiving VKAs who presented with acute major bleeding. The efficacy of 4F-PCC was demonstrated by clinical assessments of bleeding and supported by laboratory measurements of INR and factor levels. The study showed that 4F-PCC is an effective alternative to plasma for the urgent reversal of VKA therapy in major bleeding events and that this 4F-PCC has an acceptable safety profile compared with plasma.

CLINICAL PERSPECTIVE

The administration of vitamin K antagonists (VKAs) for the management of thromboembolic events is associated with hemorrhagic risk. Patients presenting with acute bleeding require rapid VKA reversal, which can be achieved by administration of either plasma or prothrombin complex concentrate (containing vitamin K–dependent factors). Despite widespread use in the United States, the efficacy of plasma has not been established and is associated with safety concerns such as fluid overload. We report the findings of the first prospective, controlled, randomized, multicenter clinical trial comparing a 4-factor prothrombin complex concentrate with plasma for the urgent reversal of VKAs in patients with acute major bleeding. The study demonstrated that compared with plasma, 4-factor prothrombin complex concentrate was noninferior for the primary end point of hemostatic efficacy at 24 hours, was superior for the coprimary end point of rapid international normalized ratio reduction, and had a similar safety profile. Thus, 4-factor prothrombin complex concentrate can be considered an efficacious alternative to plasma for VKA reversal in patients presenting with major bleeding in time- and volume-critical situations. We believe that this report will be of significant interest to clinicians involved in the management of VKA-related bleeding complications because VKA remains an important anticoagulant therapy for numerous clinical conditions.

SUPPLEMENTAL MATERIAL

Supplemental table 1. Details of the EAB, DSMB and SAB

Board	Details
Endpoint Adjudication Board	The EAB consisted of 9 Adjudicators (4 hematologists, 2 emergency medicine physicians, 2 trauma surgeons, and 1 gastroenterologist). A lack of conflict of interest was ascertained.
Safety Adjudication Board	The SAB consisted of 3 voting members and 1 physician/moderator (non-voting member). The 3 voting members had experience in coagulation, anticoagulation treatments and their reversal, and cardiology. The physician moderator had experience in pharmacovigilance and risk management. A lack of conflict of interest was ascertained.
Data Safety Monitoring Board	The DSMB consisted of 4 voting expert members (3 physicians/1 biostatistician). The 3 physician members had experience in anticoagulant therapy and their reversal; the independent biostatistician had experience in clinical trials. All of them had prior DSMB experience. A lack of conflict of interest was ascertained.

Supplemental table 2. Secondary endpoints

Endpoint	Timeframe
Plasma levels of factors II, VII, IX, X and of proteins C and S	24 hours from start of infusion
Hemostatic efficacy of 4F-PCC and plasma for visible and musculoskeletal non-visible bleeding	3 and 6 hours from start of infusion
Time from start of infusion until INR correction	-
Time from randomization until INR correction	-
Total number of packed red blood cell transfusions and the proportion of patients with 1 or more PRBC transfusions	24 hours from start of infusion
Use of non-study-prescribed blood products and/or hemostatic agents	From randomization until 24 hours after infusion start
All-cause mortality	45 days after treatment
Safety and tolerability of 4F-PCC and plasma	-

Supplemental table 3. Primary rating of hemostatic efficacy: definitions for assessment

Rating	Definition	
	Visible bleeding	Non-visible bleeding
Excellent* (Effective)	Cessation of bleeding ≤ 1 hour after the end of infusion <u>and</u> no additional coagulation intervention required	<ol style="list-style-type: none"> Musculoskeletal bleeding: pain relief <u>or</u> no increase in swelling <u>or</u> unequivocal improvement in objective signs of bleeding ≤ 1 hour after the end of infusion; <u>and</u> the condition has not deteriorated during the 24-hour period ICH: $\leq 20\%$ increase in hematoma volume compared to baseline on repeat CT scan performed at the 3- and 24-hour time point Non-visible bleeding that is not described above (e.g. GI bleeding): $\leq 10\%$ decrease in both Hb/Hct[†] at 24 hours[‡] compared to baseline (initial correction of decrease in Hb with PRBCs, with a transfusion trigger of a Hb $\leq 8 \pm 1$ g/dL [i.e. transfuse PRBCs if the Hb $\leq 8 \pm 1$ g/dL])
Good§ (Effective)	Cessation of bleeding >1 and ≤ 4 hours after end of infusion <u>and</u> no additional coagulation intervention required	<ol style="list-style-type: none"> Musculoskeletal bleeding: Pain relief <u>or</u> no increase in swelling <u>or</u> unequivocal improvement in objective signs of bleeding >1 and ≤ 4 hours after the end of infusion; <u>and</u> the condition has not deteriorated during the 24-hour period ICH: $>20\%$, but $\leq 35\%$ increase in hematoma volume compared to baseline on a repeat CT scan performed at the 24-hour time point Non-visible bleeding that is not described above: >10 to $\leq 20\%$ decrease in both Hb/Hct[†] at 24 hours[‡] compared with baseline (initial correction of decrease in Hb with PRBCs, with a transfusion trigger of a Hb $\leq 8 \pm 1$ g/dL [i.e. transfuse PRBCs if the Hb $\leq 8 \pm 1$ g/dL])

Poor/None (Non-effective)	Cessation of bleeding >4 hours after end of the infusion, <u>and/or</u> additional coagulation intervention required (e.g. plasma, whole blood cell pack, or coagulation factor products)	<ol style="list-style-type: none"> 1. Musculoskeletal bleeding: no improvement by 4 hours after the end of infusion <u>and/or</u> the condition has deteriorated during the 24-hour period 2. ICH: >35% increase in hematoma volume compared to baseline on repeat CT scan performed at the 24 hour time point 3. Non-visible bleeding that is not listed above: >20% decrease in both Hb/Hct at 24 hours[‡] compared to baseline (initial correction of decrease in hemoglobin with PRBCs, with a transfusion trigger of a Hb $\leq 8 \pm 1$ g/dL [i.e. transfuse PRBCs if the Hb $\leq 8 \pm 1$ g/dL])
--	---	--

Any additional diagnostic data for a particular bleeding site, e.g. nasogastric tube, ultrasound, GI endoscope, or CT scans, were taken into account for the overall assessment. Pain, swelling and signs of bleeding were considered to be typical symptoms in cases of musculoskeletal bleeding and were expected to be present at baseline. Any uncontrolled bleeding that did not respond to 4F-PCC or plasma and was related to the underlying disease was taken into account for the overall assessment.

CT, computed tomography; GI, gastrointestinal; Hb, hemoglobin; Hct, hematocrit; ICH, intracranial hemorrhage; PRBCs, packed red blood cells

*For all types of bleeding: no additional plasma, blood products (whole blood products not including PRBCs) and/or coagulation factor products required after initial treatment with study drug; [†]The smallest percentage decrease in Hb or Hct should be used to determine the efficacy rating of excellent, good or poor/none; [‡]Assumption for the 24-hour adjusted Hb/Hct calculation: for each unit of PRBC transfusion there is generally an increase of 1 g/dL in Hb or 3% increase in Hct; [§]For all types of bleeding: no more than two additional units of plasma or blood products and/or coagulation factor products required after initial treatment with study drug; ^{||}For all types of bleeding: more than two additional units of plasma, blood products and/or coagulation factor products required after initial treatment with study drug

Supplemental table 4. Patients meeting each of the three acute major bleeding eligibility criteria (ITT-E population)

Definition	4F-PCC (N=98)		Plasma (N=104)	
	n	%	n	%
1. Life-threatening or potentially life-threatening bleeding	73	74.4	73	70.1
2. Acute bleeding associated with a fall in hemoglobin level ≥ 2 g/dL	36	36.7	34	29.8
3. Bleeding requiring blood product transfusion (blood products include plasma, red blood cells and other coagulation factor products)	71	72.4	82	78.8

Supplemental table 5. Length of hospital stay (ITT-E population)

Parameter	4F-PCC (N=98)		Plasma (N=104)	
	Median	IQR	Median	IQR
Inpatient time (hours)	107.9	71.6-151.3	101.4	67.4-146.9
Emergency department time (hours)	4.9	0-8.7	5.0	0-9.4
Intensive care unit / critical care unit (hours)	0	0-44.7	0	0-40.0
General floor time (hours)	71.1	31.1-146.5	67.9	21.0-136.5

Supplemental table 6. Primary rating of hemostatic efficacy by type of major bleeding (ITT-E population)

Type of bleeding	Hemostatic efficacy rating	4F-PCC (N=98)		Plasma (N=104)		2-sided p-value*
		n	%	n	%	
Gastrointestinal	Excellent or good	41	74.5	44	75.9	0.8718
	Poor or none	14	25.5	14	24.1	
Visible	Excellent or good	12	75.0	12	57.1	0.2662
	Poor or none	4	25.0	9	42.9	
ICH	Excellent or good	5	41.7	7	58.3	0.4241
	Poor or none	7	58.3	5	41.7	
Musculoskeletal	Excellent or good	7	100	2	28.6	0.0072
	Poor or none	0	0	5	71.4	
Other non-visible	Excellent or good	6	75.0	3	50.0	0.3519
	Poor or none	2	25.0	3	50.0	

*Cochran-Mantel-Haenszel

Note: due to the small numbers of patients involved in some categories, it is probable that there was insufficient power to detect differences between groups; 4F-PCC, four-factor prothrombin complex concentrate; ICH, intracranial hemorrhage; N, total number of patients; n, number of patients within subtype group

Supplemental table 7. Hemostatic efficacy by country/region (ITT-E population)

		4F-PCC (N=98)		Plasma (N=104)		Two-sided p-value
		n	%	n	%	(Cochran-Mantel-Haenszel)
Europe	Excellent or good	20	66.7	22	68.8	0.86
	Poor/none	10	33.3	10	31.3	
United States	Excellent or good	51	75.0	46	63.9	0.16
	Poor/none	17	25.0	26	36.1	

Breslow Day test for 3-way interaction of region by treatment by outcome was 0.343. Results for both regions are not significantly different.

Supplemental table 8. Rapid reduction of INR (≤ 1.3 at 0.5 hours after the end of infusion) by country/region (ITT-E population)

		4F-PCC (N=98)		Plasma (N=104)		Two-sided p-value
		n	%	n	%	(Cochran-Mantel-Haenszel)
Europe	Rapid reduction	15	50.0	1	3.1	<0.0001
	No rapid reduction	15	50.0	31	96.9	
United States	Rapid reduction	46	67.6	9	12.5	<0.0001
	No rapid reduction	22	32.4	63	87.5	

Breslow Day test for 3-way interaction of region by treatment by outcome was 0.510. Results for both regions are not significantly different.

Supplemental table 9. Hemostatic efficacy (ITT population)

Primary rating	Number (%) of patients [95% CI]		Difference 4F-PCC – plasma (%) [95% CI]
	4F-PCC (N=107)	Plasma (N=109)	
Hemostatic efficacy rating by category*			
Excellent	46† (43.0)	46† (42.2)	
Good	28 (26.2)	26 (23.9)	
Poor/none	33 (30.8)	37 (33.9)	
<i>Non-effective</i>	<i>26 (24.3)</i>	<i>33 (30.3)</i>	
<i>Missing primary rating</i>	<i>7 (6.5)</i>	<i>4 (3.7)</i>	
'Effective' hemostasis	74 (69.2)	72 (66.1)	3.1‡
	[60.4; 77.9]	[57.2; 74.9]	[-9.4; 15.6]

*Hemostatic efficacy assessed by a blinded independent board; †p-value=0.75 by Cochran-Mantel-Haenszel test; ‡4F-PCC non-inferior to plasma;

Effective hemostasis, hemostatic efficacy rated as excellent or good; 4F-PCC, four-factor prothrombin complex concentrate; CI, confidence interval

Supplemental table 10. Rapid INR reduction (ITT population)

	Number (%) of patients [95% CI]		Difference 4F-PCC –
	4F-PCC (N=107)	Plasma (N=109)	plasma (%) [95% CI] [†]
Rapid decrease of INR*	64 (59.8)	10 (9.2)	50.6
	[50.5; 69.1]	[3.8; 14.6]	[37.9; 63.4]

*INR ≤1.3 at 0.5 h after the end of infusion; [†]4F-PCC non-inferior to plasma: lower limit of 95% CI >−10%; 4F-PCC superior to plasma: lower limit of 95% CI

>0; 4F-PCC, four-factor prothrombin complex concentrate; CI, confidence interval; N, total number of patients

Supplemental table 11. Number of patients with SAEs by preferred term to Day 45 visit (ITT-S population)

Preferred term*	Number (%) of patients	
	4F-PCC (N=103)	Plasma (N=109)
Any SAE†	32 (31.1)	26 (23.9)
Ischemic stroke	3 (2.9)	0
Pneumonia	2 (1.9)	1 (0.9)
Respiratory failure	2 (1.9)	1 (0.9)
Hemorrhage intracranial	2 (1.9)	0
Atrial flutter	2 (1.9)	0
Cardiac failure congestive	1 (1.0)	4 (3.7)
Encephalopathy	0	2 (1.8)
Subarachnoid hemorrhage	0	2 (1.8)
Myocardial ischemia	0	2 (1.8)
Anemia	0	2 (1.8)
Related SAE‡	2 (1.9)	4 (3.7)
Deep vein thrombosis	1 (1.0)	0
	(Onset day: 13)	
Ischemic stroke	1 (1.0)	0
	(Onset day: 43)	
Myocardial ischemia	0	2 (1.8)
		(Onset day: 1, both patients)
Fluid overload	0	1 (0.9)
		(Onset day: 3)
Respiratory failure	0	1 (0.9)
		(Onset day: 1)

*Listed in descending order based on frequency in 4F-PCC group and coded according to MedDRA 12.0; multiple SAE entries per patient possible. †SAEs reported for >1 patient per group; ‡Defined as events whose relationship to study treatment was related in the opinion of the investigator

Supplemental table 12. Number of patients with fluid overload or cardiac events (ITT-S population)

Parameter	4F-PCC (N=103)		Plasma (N=109)	
	n	%	n	%
Any fluid overload or similar cardiac events	5	4.9	14	12.8
Fluid overload	0	0	4	3.7
Pulmonary edema	2	1.9	4	3.7
Cardiac failure				
Cardiac failure congestive	2	1.9	5	4.6
Cardiac failure	1	1.0	1	0.9
Cardiac failure chronic	0	0	1	0.9

Supplemental table 13. Listing of patients who died up to Day 45 (ITT-S population)

Cause of death (reported term)	Study day	Age (years)	Comfort care	Relationship to treatment (as adjudicated by the SAB)
4F-PCC group (N=10)				
Increased size of intracranial hemorrhage	3	82	Yes	Not related
Gradual worsening of cardiogenic heart failure	5	75	Yes	Not related
Sudden death	7	56	No	Possibly related
Sepsis (staph infection uncertain etiology)	26	66	Yes	Not related
Acute renal failure	19	71	Yes	Not related
Pancreatic cancer	30	84	Yes	Not related
Cardiopulmonary arrest	31	54	No	Not related
Respiratory failure	33	79	Yes	Not related
Stage IV lung cancer	34	73	Yes	Not related

Plasma group (N=5)				
Systemic infection	4	89	Yes	Not related
Worsening metastatic lung cancer	7	85	Yes	Not related
Progression of hemorrhagic anemia	7	80	No	Not related
Sepsis shock	14	80	Yes	Not related
Worsening hepatic failure	24	72	Yes	Not related

Supplemental table 14. Definitions of non-serious AEs and SAEs

Event type	Definition
Serious adverse event (SAE)	<p data-bbox="450 341 2007 517">Any untoward medical occurrence that at any dose: resulted in death; was life-threatening; required in-patient hospitalization or prolongation of existing hospitalization; resulted in persistent or significant disability/incapacity; was a congenital anomaly/birth defect; was according to investigator’s judgment another medically important condition.</p> <p data-bbox="450 555 2007 874">Important medical events that did not result in death, were not life-threatening, or did not require hospitalization could have been considered an SAE when, based upon appropriate medical judgment, they had jeopardized the patient and required medical or surgical intervention to prevent one of the outcomes listed in the definition. Examples of such medical events include allergic bronchospasms requiring intensive treatment in an emergency department (ED) or at home, convulsions that do not result in in-patient hospitalization, or the development of drug dependency or drug abuse.</p> <p data-bbox="450 912 2047 1091">“Life-threatening” meant that the patient was at immediate risk of death from the AE as it occurred. It did not include an AE that, had it occurred in a more severe form, might have caused death. “Requires in-patient hospitalization” was to be defined as hospital admission required for treatment of the AE. Hospital admission for scheduled elective surgery was not an SAE.</p>
Non-serious adverse event	AEs which did not fulfil the criteria for an SAE were defined as non-serious AEs
