

COMMENTARY

Time to look beyond one-year mortality in critically ill hematological patients?

Ine Moors¹ and Dominique D Benoit^{2*}

Abstract

The spectacular improvement in long-term prognosis of patients with hematological malignancies since the 1980s, coupled with the subsequent improvement over the past decade in short- and mid-term survival in cases of critical illness, resulted in an increasing referral of such patients to the ICU. A remaining question, however, is how these patients perform in the long term with regard to survival and quality of life. Here we discuss the present multicenter study on survival beyond 1 year in critically ill patients with hematological malignancies. We conclude with suggestions on how we can further improve the long-term outcome of these patients.

The long-term survival of patients with hematological malignancies has improved dramatically over the past decades. Nowadays, about 40% of patients with acute leukemia or high-grade non-Hodgkin lymphoma survive for more than 5 years and about 30% of these patients can be cured. Unfortunately, owing to their underlying disease or treatment or both, these patients are at high risk of severe complications, often requiring transfer to the ICU. Historically, intensivists have been reluctant to admit these patients to the ICU because of the almost uniformly fatal prognosis reported in the literature in patients with evolving organ dysfunction requiring mechanical ventilation, vasopressors, or renal replacement therapy alone or in combination. Over the past decade, several centers around the world that specialize in the management of these patients have clearly shown that these grim prognostic estimates no longer hold and that the reluctance to admit these patients to the ICU,

is simply because of their underlying malignancy, is no longer justified. This has resulted in an increasing referral of such patients to the ICU. An important remaining question, however, is how these patients perform in the long term with regard to survival and quality of life.

In a study in the previous issue of *Critical Care*, Bernal and colleagues [1] focused on the determinants of survival beyond 1 year in a multicenter setting. As could be expected from what we observed at the bedside, functional status (Eastern Cooperative Oncology Group performance status of more than 2), relapsing hematological malignancy, and absence of compliance with the scheduled therapy for the underlying disease after ICU discharge were associated with a worse survival. However, what was less expected is that the survival reached nearly 0% after 1.5 years if only one of these factors was present. Of note, only 62 patients were included in this study, and depending on whether we focus on a half-empty or half-full glass, the other half of the patients achieved a 5-year post-ICU survival of 40% to 50%. In the largest study ever published, including more than 1,000 patients with hematological malignancies admitted over a 16-month period in 17 specialized centers in France and Belgium, hospital survival was 60.7%; up to 80% of these patients had no change in treatment intensity, and 80% were in complete or partial remission 6 months after ICU discharge [2]. Moreover, recent studies have shown that ICU admission does not influence long-term outcome in patients with acute myeloid leukemia who survive the first 30 days after ICU discharge: they had similar survival and complete remission rates up to 3 years [3] and 6 years [4], respectively, after discharge in comparison with acute myeloid leukemia patients for whom ICU admission was not necessary. Therefore, what the study by Bernal and colleagues [1] shows above all is that being technically skilled in advanced life-support therapies is not enough to improve long-term outcome; as intensivists, we also have to acknowledge better when to use these therapies and when we have to withdraw them during ICU stay [5].

Full list of author information is available at the end of the article

More than ever, long-term estimations with regard to survival and quality of life should be taken into account upon referral to the ICU [5,6]. Only close collaboration and in-depth communication between hematologists and intensivists upon referral and during ICU stay can bridge the two extremes of the overoptimistic oncologists who often overestimate the long-term survival of their patients in daily practice [7,8] and the overpessimistic intensivists who are reluctant to admit them. Such an open and constructive atmosphere, in which physicians assume a leading role, disseminate a clear vision, and let other team members, the patients, and relatives actively and safely participate in the decision-making processes [9,10], will not only improve the average long-term outcome of published series focusing on any severe underlying comorbidity but also reduce the burden for individual patients and their relatives at the bedside [5,11]. Health-care workers will also benefit, since real or perceived disproportionate care in the ICU leads to acute or, much worse, more subtle chronic conflicts within the team, resulting in poor quality of care [5,9,10,12]. The latter is particularly deleterious since it will affect the patient's short- and long-term outcome in general, regardless of whether the admission is justified or not.

Conclusions

A good admission policy is necessary in order to safeguard the quality of ICU care provided to patients with good long-term expectations on the one hand and to reduce the burden for patients and relatives with poor long-term expectations on the other. This can be achieved only by creating working environments enhancing close collaboration and communication between intensivists and hematologists and where the patient and relatives are closely involved in the decision-making process upon ICU referral and during ICU stay. It is important to note that this holds not only for patients with hematological malignancies such as in the study by Bernal and colleagues [1] but also for patients with any other severe underlying comorbidity that are increasingly referred to the ICU.

Abstract

Introduction

Although the survival rates of hematological patients admitted to the ICU are improving, little is known about the long-term outcome. Our objective was to identify factors related to long-term outcome in hematological patients after ICU discharge.

Methods

A prospective, observational study was carried out in seven centers in Spain. From an initial sample of 161 hematological patients admitted to one of the participating ICUs during the study period, 62 were discharged alive and followed for a median time of 23 (1 to 54) months. Univariate and multivariate analysis were performed to identify the factors related to long term-survival. Finally, variables that influence the continuation of the scheduled therapy for the hematological disease were studied.

Results

Mortality after ICU discharge was 61%, with a median survival of 18 (1 to 54) months. In the multivariate analysis, an Eastern Cooperative Oncology Group score (ECOG) >2 at ICU discharge (Hazard ratio 11.15 (4.626 to 26.872)), relapse of the hematological disease (Hazard ratio 9.738 (3.804 to 24.93)) and discontinuation of the planned treatment for the hematological disease (Hazard ratio 4.349 (1.286 to 14.705)) were independently related to mortality. Absence of stem cell transplantation, high ECOG and high Acute Physiology and Chronic Health Evaluation II (APACHE II) scores decreased the probability of receiving the planned therapy for the hematological malignancy.

Conclusions

Both ICU care and post-ICU management determine the long-term outcome of hematological patients who are discharged alive from the ICU.

Introduction

Hematological patients admitted into an intensive care unit (ICU) experience high mortality rates. In response to this clinical problem, research has helped to identify prognostic factors related to intra-ICU and intra-hospital mortality. The result has been an improvement in the outcome over the last decade [1] as a consequence of a number of factors, including implementation of non-invasive mechanical ventilation [2], earlier intervention in septic shock [3] and better management of specific complications (such as tumor lysis syndrome) [4]. As most of the research has focused on intra-ICU or intra-hospital mortality, information regarding survival is limited to this period. More recently, some groups have extended the follow up period to 6–12 months after the patients have been discharged from ICU [5-10], but data regarding long-term survival (more than one year after ICU discharge) is scarce. This raises a concern about the validity of the classical predictive factors for intra-ICU or in-hospital mortality in predicting long-term survival. For instance, the need for mechanical ventilation is a well-known risk factor for ICU death, but its impact in long-term survival is largely unknown.

Moreover, there is an increasing concern on the general conditions of the patients at ICU discharge, including nutritional, neuromuscular and cognitive status. These factors, which are amenable to intervention and may impact the long-term survival and quality of life in unselected ICU patients, would be also relevant in a fragile population such as those with hematological malignancies. In addition, factors that determine the feasibility of subsequent chemotherapy cycles after ICU discharge and their impact in the long-term control of the neoplastic disease have not been studied.

Here we report on long-term outcome in a population of hematological patients that survived an ICU admission and analyze the clinical factors influencing survival. We hypothesized that both intra-ICU and after-ICU variables could determine the suitability of a patient for receiving additional therapies, therefore determining the long-term outcome of this population. To test this hypothesis, we studied classical prognostic factors (such as mechanical ventilation, organ failure, neutropenia), as well as those related to the underlying disease and its evolution. In particular, we have analyzed the applicability of chemotherapy after ICU discharge and its relevance on hematological relapse and survival.

Methods

The EMEHU (*Estudio Multicéntrico del Enfermo Hematológico en UCI*) study included all the hematological patients (including those with neoplastic or non-neoplastic diseases), admitted due to medical or surgical reasons to one of 34 intensive care units in Spain during the June 2007-September 2008 period [11]. From the 450 patients included in the EMEHU database, 215 were discharged alive. Among these, 67 patients were discharged from one of the seven units participating in this substudy. Patients discharged for palliative care were not included in the study. This resulted in a final sample of 62 ICU survivors, that constitutes the object of this investigation (Figure 1). To exclude a selection bias, a comparison was made between the patients included in the study and those from the non-participating centers. There were no differences in age, gender, hematological diagnosis, stage of the disease, percentage of transplanted patients, APACHE-II score at ICU admission or mortality (data not shown).

Figure 1 Patients included in the EMEHU study and subpopulation included in the present study.

The study was approved by local Ethics committees (see Acknowledgements) and written informed consent was obtained for each participant.

Data collection

The EMEHU database included data on demographics, hematological disease, diagnosis at ICU admission, severity scores, treatments, infections and complications during their ICU stay. Neutropenia was defined as an absolute neutrophil count below $0.5 \times 10^9 L^{-1}$ [12]. During the follow-up period after ICU discharge, data on Eastern Cooperative Oncology Group (ECOG) score [13], relapse and treatment for the hematological disease were collected. According to the compliance with the pre-planned treatment for each hematological disease, four groups of patients were predefined: 1: Those who did not require additional treatment (i.e. patients in complete remission or transplanted patients without planned maintenance treatment); 2: Patients who required and received full-dose treatment; 3: Patients who required treatment and received it with modifications (reduced doses or delays); and 4: Patients who required treatment but did not receive it. In these last cases, reasons for the changes in the therapeutic plan were recorded.

Statistical analysis

Normality of all variables was studied using the Kolmogorov-Smirnov test. Data are expressed as mean \pm standard deviation or median (range) for variables with or without a normal distribution respectively. Univariate comparisons between survivors and non-survivors after ICU discharge were performed using Student's T-tests, Mann-Whitney's U-tests or chi-square tests. Those variables with a p value for the difference lower than 0.05 were included in the multivariate survival analysis. In order to deal with time-dependent variables (i.e. relapse), we used an extended Cox regression model. Hazard ratios (HR) with their 95% confidence intervals were computed. A p value lower than 0.05 in this multivariate analysis was considered significant. To evaluate the accuracy of the model over time, area under the incident/dynamic ROC curve (AUC) was computed [14].

The four groups of patients resulting from the previously described classification based on the compliance with the pre-planned treatment were compared using a one-way ANOVA, Kruskal-Wallis' ANOVA or chi-square tests, as appropriate. In order to look for optimal classification criteria, significant variables were included in a decision tree analysis. In particular, the Chi-square Automated Interaction Decision (CHAID) algorithm was used, and variables with a p value lower than 0.05 were considered significant.

Results

General characteristics of the sample

During the study period, the seven participating hospitals admitted 161 patients. Sixty-two patients (39%) were discharged alive from the ICU and were analyzed. There were 36 males (59%) and 26 females (41%). Age was 53 ± 16 years. The most frequent underlying disease was acute leukemia (38% of the patients) followed by lymphoma (24%). Most of the patients with acute leukemia were receiving remission-induction chemotherapy prior to ICU admission. Patients were transferred to the ICU from the emergency department in 18 cases (29%) or from the hospital ward in 44 cases (71%). The most common cause of ICU admission was acute respiratory failure (44% of the patients) followed by sepsis (35%) or shock (27%). There was only one surgical patient (laparotomy due to perforated typhlitis), all the others being admitted due to medical reasons. All these characteristics of the study population are summarized in Table 1.

Table 1 Characteristics of the study population

Data are shown as number (percentage) or mean \pm standard deviation. *One patient with paroxysmal nocturnal hemoglobinuria cannot be included in this classification.

Patients were followed for a median time of 23 months (range 1–54). Thirty-seven patients (59%) died after ICU discharge, with a median overall survival of 18 months (range 1–54). Median follow up time for survivors was 43 months (11–54). Figure 2 shows the survival curve for the study population.

Figure 2 Overall survival of the whole population after ICU discharge (continuous black line) with 95% confidence intervals (dotted gray lines).

Risk factors for mortality after ICU discharge

First, a univariate analysis comparing survivors and non-survivors after ICU discharge was performed (Table 2). There were no differences in age or sex between these groups. Among the comorbid conditions, only a diagnosis of arterial hypertension was related to mortality. Regarding the hematological disease, there were no significant differences in mortality rates according to the main diagnosis, although there was a non-significant trend towards lower mortality rates in patients with lymphoma (HR 0.355 [0.125-1.006]). Similarly, stage of the disease, referral site of the patient (emergency room or hospital ward) or history of stem cell transplantation were not related to survival. Presence of neutropenia before or during the ICU stay was associated with a poor outcome. In fact, both variables were closely correlated. Therefore, we only considered neutropenia during the ICU stay (HR 2,024 [1.042-3.937]) for inclusion in the multivariate analysis.

Table 2 Results of the univariate analysis studying the differences in variables collected before ICU discharge between long-term survivors and non-survivors

	Alive	Dead	p
	N = 26	N = 36

Length of NIMV [median (range), days]	0 (0–12)	0 (0–12)	0.60
Length of pre-ICU stay [median (range), days]	5 (0–66)	3 (0–26)	0.43
Length of ICU stay [median (range), days]	5 (1–58)	7 (1–68)	0.54
ECOG at ICU discharge			0.001
0-2	25	22	
3-4	1	14	

Data are shown as number, mean ± standard deviation (SD) or median (range) for normally and non-normally distributed variables respectively. *MDS* Myelodysplastic syndrome, *cMPN* Chronic myeloproliferative neoplasms, *CLL* Chronic lymphocytic leukemia, *MV* Mechanical ventilation, *NIMV* Non-invasive mechanical ventilation. *One patient with paroxysmal nocturnal hemoglobinuria cannot be included in this classification.

Among the data collected during the ICU stay, there were no differences between survivors and non-survivors in causes of admission, APACHE-II score, days of mechanical ventilation (either invasive or non-invasive) or complications during this period (data not shown). However, a high ECOG at ICU discharge score was significantly related to mortality (HR 7.28. [3.572-14.850] for ECOG 3–4).

Finally, variables collected after ICU discharge were analyzed. There were significant differences in the relapse of the hematological disease (2 vs 14 cases in survivors and non-survivors respectively, chi-square $p = 0.007$). Compliance with treatment for the

hematological disease also yielded statistically significant differences between survivors and non-survivors: Only 5 out of 26 survivors did not follow the previously planned therapeutic schedule, in contrast to 18 out of 36 among non-survivors (chi-square $p = 0.02$).

The five variables with a p value lower than 0.05 were included in a multivariate model (Table 3 and Figure 3). In this analysis, relapse (Figure 3A), ECOG score at ICU discharge (Figure 3B) and compliance with the scheduled treatment for the hematological disease (Figure 3C) were significantly related to post-ICU mortality. The accuracy of this model was evaluated over time by estimation of the area under the ROC curve (Figure 3D). As shown, the accuracy was good immediately after ICU discharge (AUC 0.90) and decreased to 0.77, 0.74 and 0.72 after one, two and three years respectively.

Table 3 Multivariate analysis for survival

	HR	95% Confidence interval
ECOG > 2 at ICU discharge	11.150	4.626-26.872
Relapse after ICU discharge	9.738	3.804-24.93
Compliance with therapy		
Finished treatment pre-ICU	1	
Full treatment	1.075	0.319-3.622
Dose reduction or delay	2.172	0.629-7.501
No treatment	4.349	1.286-14.705

HR Hazard ratio.

Figure 3 Survival curves. Estimated survival curves according to the Cox regression model showing the impact of relapse (A), ECOG (B) and each therapeutic group (no need for further treatments, treatment received without changes or delays, treatment received with dose reductions or delays, treatment needed but not received, C). The accuracy of the regression model, measured as the area under the ROC curve (AUC), over time is shown in panel D.

Therapeutic strategies after ICU discharge

Considering the impact of post-ICU treatment on survival we analyzed factors that determined the probability of patients to receive pre-planned treatment for hematological disease. Among the 62 studied patients, 15 did not need further treatment, 24 patients completed the pre-planned treatment after ICU discharge, 12 patients received treatment with dose reductions or delays (4 due to infection and the rest due to medical decision) and 11 patients did not receive treatment for their hematological disease, all due to medical decision.

The differences among these groups were studied using a decision tree analysis. The three variables that yielded significant differences were stem cell transplant, ECOG at ICU discharge and APACHE-II score (Figure 4). As expected, most transplanted patients did not require more treatment after ICU discharge. However, patients with ECOG >2 at ICU discharge, and specifically those with an APACHE-II score above 21, received treatment with dose reductions or delays or discontinued the treatment more frequently.

Figure 4 Decision tree analysis showing the variables that significantly discriminate among the different therapeutic groups.

Discussion

In this work we have analyzed the evolution of a cohort of hematological patients after an ICU stay in order to identify the factors related to long-term survival after ICU discharge. Although the sample size of our study could result in a low statistical power, the robust statistical analysis used, including uni- and multivariate analysis and restrictive cut-off points, have helped to identify some relevant variables related to long-term outcome. In this sense, a ECOG score > 2 at ICU discharge, the relapse of the hematological neoplasm and the absence of compliance with the scheduled therapy for the underlying disease after ICU discharge predicted a worse survival in this cohort. However, it must be recognized that other variables may have not been detected due to the sample size. In this sense, larger studies will be required to validate our findings.

The need of data on long-term survival of hematological patients after ICU discharge has been recently highlighted due to their increased acceptance in ICUs [15], the survival improvements [1] and the awareness on resource consumption [16,17]. Our work presents data after a median follow-up time of 23 months, with 59% mortality and a median survival of 18 months.

As most of the previously published studies dealing with critically-ill hematological patients are limited to follow-up period of 6–12 months [5-9,18], our results are difficult to compare. In spite of this limitation, high mortality rates after ICU discharge have been uniformly described. This high number of deaths must be added to the high ICU mortality of this population (about 40-50% in the published literature [5-8,10], 61% in our series). Nonetheless, these findings were expected, as both an ICU stay [19] and a diagnosis of a hematological neoplasm are risk factors for death in the general population. Moreover, the most prevalent hematological diagnosis in our cohort was acute leukemia during the induction phase, a condition with high-risk for infections and death [20]. Due to the diagnostic heterogeneity of our sample we cannot properly assess how the ICU stay modifies the course of these diseases. With this limitation in mind, we can compare our survival rates with an unselected population of patients with acute myeloid leukemia [21]. Our data show a 1-year mortality higher than the 10-15% reported for the unselected population. However, long-term survival in our study is about 40%, which is not very different from 50% reported for the whole cohort of leukemic patients. The impact of an ICU stay in the course of specific diseases should be addressed in future studies.

The three predictive factors for survival in our study were ECOG at ICU discharge, relapse of hematological disease and adherence to the planned therapy after discharge. ECOG is a simple and easily applicable score that reflects the patient response to the tumor and quantifies the performance status of the subject. It has demonstrated a prognostic value in virtually all hematological neoplasms, independently of other clinical and biological variables [22-25]. In the context of this study, it is reasonable to think that the consequences of intensive therapies required during ICU stay may have impact on final ECOG at ICU discharge. A recent large cohort have demonstrated that a poor performance status is related to a increased risk of intra-hospital death [10]. The second prognostic factor for survival is relapse of underlying disease. This is not a surprising result, considering that relapse confers a kind of resistance to chemotherapy that is exceptionally difficult to overcome except with aggressive therapies, like stem cell transplantation [26]. Finally, discontinuation of the scheduled treatment for the hematological disease is the third factor related to a poor

outcome. This risk is partially avoided when treatment is given even with dose reductions or delays.

Due to the relevance of this last factor, which has not been explored previously, we focused on the variables that could predict the adherence to the subsequent hematological treatment. The decision tree analysis allows to identify the most relevant parameters that determine allocation to one group. The first variable that determines the probability of treatment continuation was stem cell transplantation. As expected, patients after stem cell transplantation or those in complete remission do not need further treatment for their disease, and show a good prognosis after ICU discharge. Conversely, those in the remission induction phase or with a relapse usually need additional treatments. It must be noted that up to 50% of the patients in the remission-induction phase do not receive full treatment after ICU discharge. In these patients, ECOG appears again as a critical factor that discriminates among groups with different probabilities of receiving a complete chemotherapy treatment. According to our previous discussion, patients with an ECOG >2 at ICU discharge have a substantially decreased functional reserve that hampers their capacity to tolerate an aggressive treatment like chemotherapy. This finding highlights the critical importance of strategies aimed to minimize the negative impact of ICU stay and preserve the patients' status [27]. Finally, APACHE-II allows further discrimination among the patients with high ECOG scores. A high APACHE-II score decreased the probability of continuation of therapy once the patient has been discharged from the ICU. It has been demonstrated that early ICU admission improves the outcome in this population [10,28]. The admission before the development of multiple organ dysfunction could be related to lower APACHE-II scores and a better compliance with the treatment after ICU discharge, thus improving the long-term outcome. However, our data does not allow to identify other factors that may have special relevance, such as specific organ failures responsible for the medical reasons behind the changes in the therapeutic plan.

Collectively our study suggests that management of critical hematological patients goes beyond the ICU and represents a challenge for both hematologists and intensivists: once a hematological patient is admitted in the ICU, physicians should consider the need to follow the therapeutic plan and not only the immediate risk of death. Previous studies have demonstrated that, when needed, continuation of the chemotherapeutic regimen after ICU admission could improve the outcome of these patients [29]. Our results extend this observation, and suggest that an active therapeutic strategy must be taken after ICU discharge. If this goal cannot be accomplished, the ICU stay could be an exercise of futility due to the high risk of death after discharge. These findings should be taken into account when considering readmission of one of these patients, due to the poor outcome of those discharged alive but unable to continue their treatment.

Conclusions

Our results show that outcome of hematological patients that are discharged alive from the ICU depends on their functional status and the adherence to the planned therapy for their disease. Moreover, these two factors are closely related. These findings illustrate the relevance of strategies to reduce the consequences of an ICU stay and add new parameters to consider in the management of this fragile population.

Key messages

- Performance status, relapse of the hematological disease and continuation of the scheduled treatment for the hematological disease are the key factors that determine long-term survival of hematological patients after a ICU stay.
- The ability to continue the planned treatment for the hematological disease depends on performance status and APACHE-II score. Patients who have completed the stem cell transplant procedure or do not need more treatment have a good outcome.
