EARLY GOAL-DIRECTED THERAPY IN THE TREATMENT OF SEVERE SEPSIS AND SEPTIC SHOCK

EMANUEL RIVERS, M.D., M.P.H., BRYANT NGUYEN, M.D., SUZANNE HAVSTAD, M.A., JULIE RESSLER, B.S., ALEXANDRIA MUZZIN, B.S., BERNHARD KNOBLICH, M.D., EDWARD PETERSON, PH.D., AND MICHAEL TOMLANOVICH, M.D., FOR THE EARLY GOAL-DIRECTED THERAPY COLLABORATIVE GROUP*

ABSTRACT

Background Goal-directed therapy has been used for severe sepsis and septic shock in the intensive care unit. This approach involves adjustments of cardiac preload, afterload, and contractility to balance oxygen delivery with oxygen demand. The purpose of this study was to evaluate the efficacy of early goal-directed therapy before admission to the intensive care unit.

Methods We randomly assigned patients who arrived at an urban emergency department with severe sepsis or septic shock to receive either six hours of early goal-directed therapy or standard therapy (as a control) before admission to the intensive care unit. Clinicians who subsequently assumed the care of the patients were blinded to the treatment assignment. In-hospital mortality (the primary efficacy outcome), end points with respect to resuscitation, and Acute Physiology and Chronic Health Evaluation (APACHE II) scores were obtained serially for 72 hours and compared between the study groups.

Results Of the 263 enrolled patients, 130 were randomly assigned to early goal-directed therapy and 133 to standard therapy; there were no significant differences between the groups with respect to base-line characteristics. In-hospital mortality was 30.5 percent in the group assigned to early goal-directed therapy, as compared with 46.5 percent in the group assigned to standard therapy ($P=0.009$). During the interval from 7 to 72 hours, the patients assigned to early goal-directed therapy had a significantly higher mean ($\pm$SD) central venous oxygen saturation (70.4$\pm$10.7 percent vs. 65.3$\pm$11.4 percent), a lower lactate concentration (3.0$\pm$4.4 vs. 3.9$\pm$4.4 mmol per liter), a lower base deficit (2.0$\pm$6.6 vs. 5.1$\pm$6.7 mmol per liter), and a higher pH (7.40$\pm$0.12 vs. 7.36$\pm$0.12) than the patients assigned to standard therapy ($P\leq0.02$ for all comparisons). During the same period, mean APACHE II scores were significantly lower, indicating less severe organ dysfunction, in the patients assigned to early goal-directed therapy than in those assigned to standard therapy (13.0$\pm$6.3 vs. 15.9$\pm$6.4, $P<0.001$).

Conclusions Early goal-directed therapy provides significant benefits with respect to outcome in patients with severe sepsis and septic shock. (N Engl J Med 2001;345:1368-77.)

THE systemic inflammatory response syndrome can be self-limited or can progress to severe sepsis and septic shock.[1] Along this continuum, circulatory abnormalities (intravascular volume depletion, peripheral vasodilatation, myocardial depression, and increased metabolism) lead to an imbalance between systemic oxygen delivery and oxygen demand, resulting in global tissue hypoxia or shock.[2] An indicator of serious illness, global tissue hypoxia is a key development preceding multiorgan failure and death.[2] The transition to serious illness occurs during the critical "golden hours," when definitive recognition and treatment provide maximal benefit in terms of outcome. These golden hours may elapse in the emergency department,[3] hospital ward,[4] or the intensive care unit.[5]

Early hemodynamic assessment on the basis of physical findings, vital signs, central venous pressure,[6] and urinary output[7] fails to detect persistent global tissue hypoxia. A more definitive resuscitation strategy involves goal-oriented manipulation of cardiac preload, afterload, and contractility to achieve a balance between systemic oxygen delivery and oxygen demand.[2] End points used to confirm the achievement of such a balance (hereafter called resuscitation end points) include normalized values for mixed venous oxygen saturation, arterial lactate concentration, base deficit, and pH.[8] Mixed venous oxygen saturation has been shown to be a surrogate for the cardiac index as a target for hemodynamic therapy.[9] In cases in which the insertion of a pulmonary-artery catheter is impractical, venous oxygen saturation can be measured in the central circulation.[10]

Whereas the incidence of septic shock has steadily increased during the past several decades, the associated mortality rates have remained constant or have decreased only slightly.[11] Studies of interventions such as immunotherapy,[12] hemodynamic optimization,[9,13] or pulmonary-artery catheterization[14] enrolled patients up to 72 hours after admission to the intensive care unit. The negative results of studies of the use of hemodynamic variables as end points ("hemodynamic

*The members of the Early Goal-Directed Therapy Collaborative Group are listed in the Appendix.

optimization"), in particular, prompted suggestions that future studies involve patients with similar causes of disease[13] or with global tissue hypoxia (as reflected by elevated lactate concentrations)[15] and that they examine interventions begun at an earlier stage of disease.[16,17]

We examined whether early goal-directed therapy before admission to the intensive care unit effectively reduces the incidence of multiorgan dysfunction, mortality, and the use of health care resources among patients with severe sepsis or septic shock.

METHODS

Approval of Study Design

This prospective, randomized study was approved by the institutional review board for human research and was conducted under the auspices of an independent safety, efficacy, and data monitoring committee.

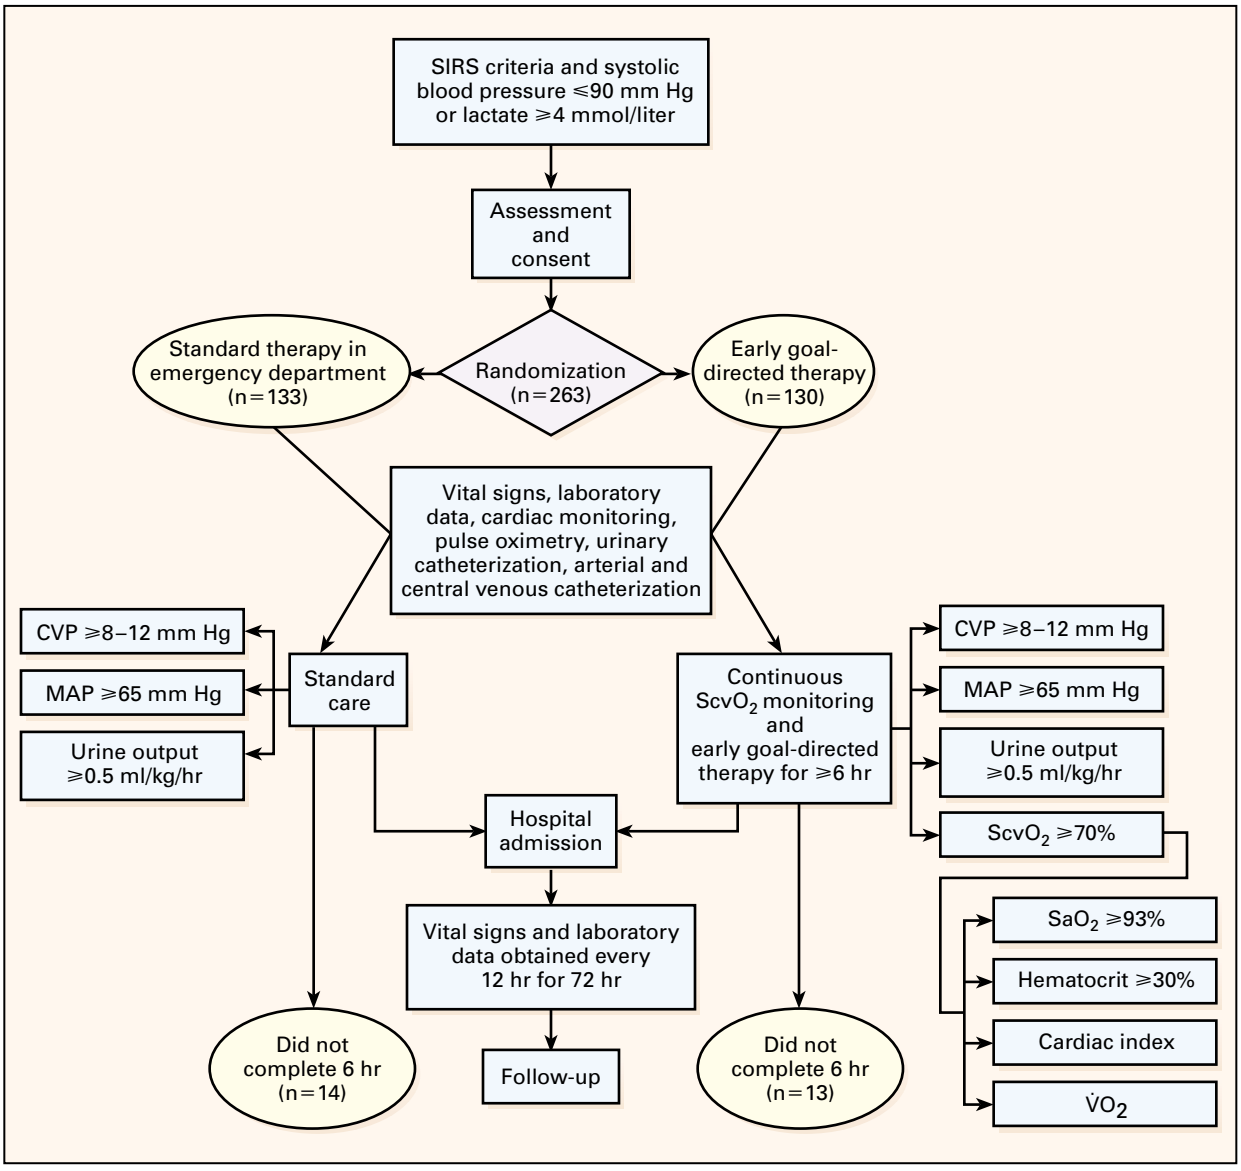

Figure 1. Overview of Patient Enrollment and Hemodynamic Support.

SIRS denotes systemic inflammatory response syndrome, CVP central venous pressure, MAP mean arterial pressure, $ScvO_2$ central venous oxygen saturation, SaO_2 arterial oxygen saturation, and $\dot{V}O_2$ systemic oxygen consumption. The criteria for a diagnosis of SIRS were temperature greater than or equal to 38°C or less than 36°C, heart rate greater than 90 beats per minute, respiratory rate greater than 20 breaths per minute or partial pressure of arterial carbon dioxide less than 32 mm Hg, and white-cell count greater than 12,000 per cubic millimeter or less than 4000 per cubic millimeter or the presence of more than 10 percent immature band forms.

Eligibility

Eligible adult patients who presented to the emergency department of an 850-bed academic tertiary care hospital with severe sepsis, septic shock, or the sepsis syndrome from March 1997 through March 2000 were assessed for possible enrollment according to the inclusion[18,19] and exclusion criteria (Fig. 1). The criteria for inclusion were fulfillment of two of four criteria for the systemic inflammatory response syndrome and a systolic blood pressure no higher than 90 mm Hg (after a crystalloid-fluid challenge of 20 to 30 ml per kilogram of body weight over a 30-minute period) or a blood lactate concentration of 4 mmol per liter or more. The criteria for exclusion from the study were an age of less than 18 years, pregnancy, or the presence of an acute cerebral vascular event, acute coronary syndrome, acute pulmonary edema, status asthmaticus, cardiac dysrhythmias (as a primary diagnosis), contraindication to central venous catheterization, active gastrointestinal hemorrhage, seizure, drug overdose, burn injury, trauma, a requirement for immediate surgery, uncured cancer (during chemotherapy), immunosuppression (because of organ transplantation or systemic disease), do-not-resuscitate status, or advanced directives restricting implementation of the protocol.

The clinicians who assessed the patients at this stage were unaware of the patients' treatment assignments. After written informed consent was obtained (in compliance with the Helsinki Declaration[20]), the patients were randomly assigned either to early goal-directed therapy or to standard (control) therapy in computer-generated blocks of two to eight. The study-group assignments were placed in sealed, opaque, randomly assorted envelopes, which were opened by a hospital staff member who was not one of the study investigators.

Treatment

The patients were treated in a nine-bed unit in the emergency department by an emergency physician, two residents, and three nurses.[3] The study was conducted during the routine treatment of other patients in the emergency department. After arterial and central venous catheterization, patients in the standard-therapy group were treated at the clinicians' discretion according to a protocol for hemodynamic support[21] (Fig. 1), with critical-care consultation, and were admitted for inpatient care as soon as possible. Blood, urine, and other relevant specimens for culture were obtained in the emergency department before the administration of antibiotics. Antibiotics were given at the discretion of the treating clinicians. Antimicrobial therapy was deemed adequate if the in vitro sensitivities of the identified microorganisms matched the particular antibiotic ordered in the emergency department.[22]

The patients assigned to early goal-directed therapy received a central venous catheter capable of measuring central venous oxygen saturation (Edwards Lifesciences, Irvine, Calif.); it was connected to a computerized spectrophotometer for continuous monitoring. Patients were treated in the emergency department according to a protocol for early goal-directed therapy (Fig. 2) for at least six hours and were transferred to the first available inpatient beds. Monitoring of central venous oxygen saturation was then discontinued. Critical-care clinicians (intensivists, fellows, and residents providing 24-hour in-house coverage) assumed the care of all the patients; these physicians were unaware of the patients' study-group assignments. The study investigators did not influence patient care in the intensive care unit.

The protocol was as follows. A 500-ml bolus of crystalloid was given every 30 minutes to achieve a central venous pressure of 8 to 12 mm Hg. If the mean arterial pressure was less than 65 mm Hg, vasopressors were given to maintain a mean arterial pressure of at least 65 mm Hg. If the mean arterial pressure was greater than 90 mm Hg, vasodilators were given until it was 90 mm Hg or below. If the central venous oxygen saturation was less than 70 percent, red cells were transfused to achieve a hematocrit of at least 30 percent. After the central venous pressure, mean arterial pressure, and hematocrit were thus optimized, if the central venous oxygen saturation was less than 70 percent, dobutamine administration was started at a dose of 2.5 μg per kilogram of body weight per minute, a dose that was increased by 2.5 μg per kilogram per minute every 30 minutes until the central venous oxygen saturation was 70 percent or higher or until a maximal dose of 20 μg per kilogram per minute was given. Dobutamine was decreased in dose or discontinued if the mean arterial pressure was less than 65 mm Hg or if the heart rate was above 120 beats per minute. To decrease oxygen consumption, patients in whom hemodynamic optimization could not be achieved received mechanical ventilation and sedatives.

Outcome Measures

The patients' temperature, heart rate, urine output, blood pressure, and central venous pressure were measured continuously for the first 6 hours of treatment and assessed every 12 hours for 72 hours. Arterial and venous blood gas values (including central venous oxygen saturation measured by in vitro co-oximetry; Nova Biomedical, Waltham, Mass.), lactate concentrations, and coagulation-related variables and clinical variables required for determination of the Acute Physiology and Chronic Health Evaluation (APACHE II) score (on a scale from 0 to 71, with higher scores indicating more severe organ dysfunction),[23] the Simplified Acute Physiology Score II (SAPS II, on a scale from 0 to 174, with higher scores indicating more severe organ dysfunction),[24] and the Multiple Organ Dysfunction Score (MODS, on a scale from 0 to 24, with higher scores indicating more severe organ dysfunction)[25] were obtained at base line (0 hours) and at 3, 6, 12, 24, 36, 48, 60, and 72 hours.[2,26] The results of laboratory tests required only for purposes of the study were made known only to the study investigators. Patients were followed for 60 days or until death. The consumption of health care resources (indicated by the duration of vasopressor therapy and mechanical ventilation and the length of the hospital stay) was also examined.

Statistical Analysis

In-hospital mortality was the primary efficacy end point. Secondary end points were the resuscitation end points, organ-dysfunction scores, coagulation-related variables, administered treatments, and the consumption of health care resources. Assuming a rate of refusal or exclusion of 10 percent, a two-sided type I error rate of 5 percent, and a power of 80 percent, we calculated that a sample size of 260 patients was required to permit the detection of a 15 percent reduction in in-hospital mortality. Kaplan–Meier estimates of mortality, along with risk ratios and 95 percent confidence intervals, were used to describe the relative risk of death. Differences between the two groups at base line were tested with the use of Student's t-test, the chi-square test, or Wilcoxon's rank-sum test. Incremental analyses of the area under the curve were performed to quantify differences during the interval from base line to six hours after the start of treatment. For the data at six hours, analysis of covariance was used with the base-line values as the covariates. Mixed models were used to assess the effect of treatment on prespecified secondary variables during the interval from 7 to 72 hours after the start of treatment.[27] An independent, 12-member external safety, efficacy, and data monitoring committee reviewed interim analyses of the data after one third and two thirds of the patients had been enrolled and at both times recommended that the trial be continued. To adjust for the two interim analyses, the alpha spending function of DeMets and Lan[28] was used to determine that a P value of 0.04 or less would be considered to indicate statistical significance.

RESULTS

Base-Line Characteristics

We evaluated 288 patients; 8.7 percent were excluded or did not consent to participate. The 263 patients enrolled were randomly assigned to undergo either standard therapy or early goal-directed therapy; 236 patients completed the initial six-hour study period.

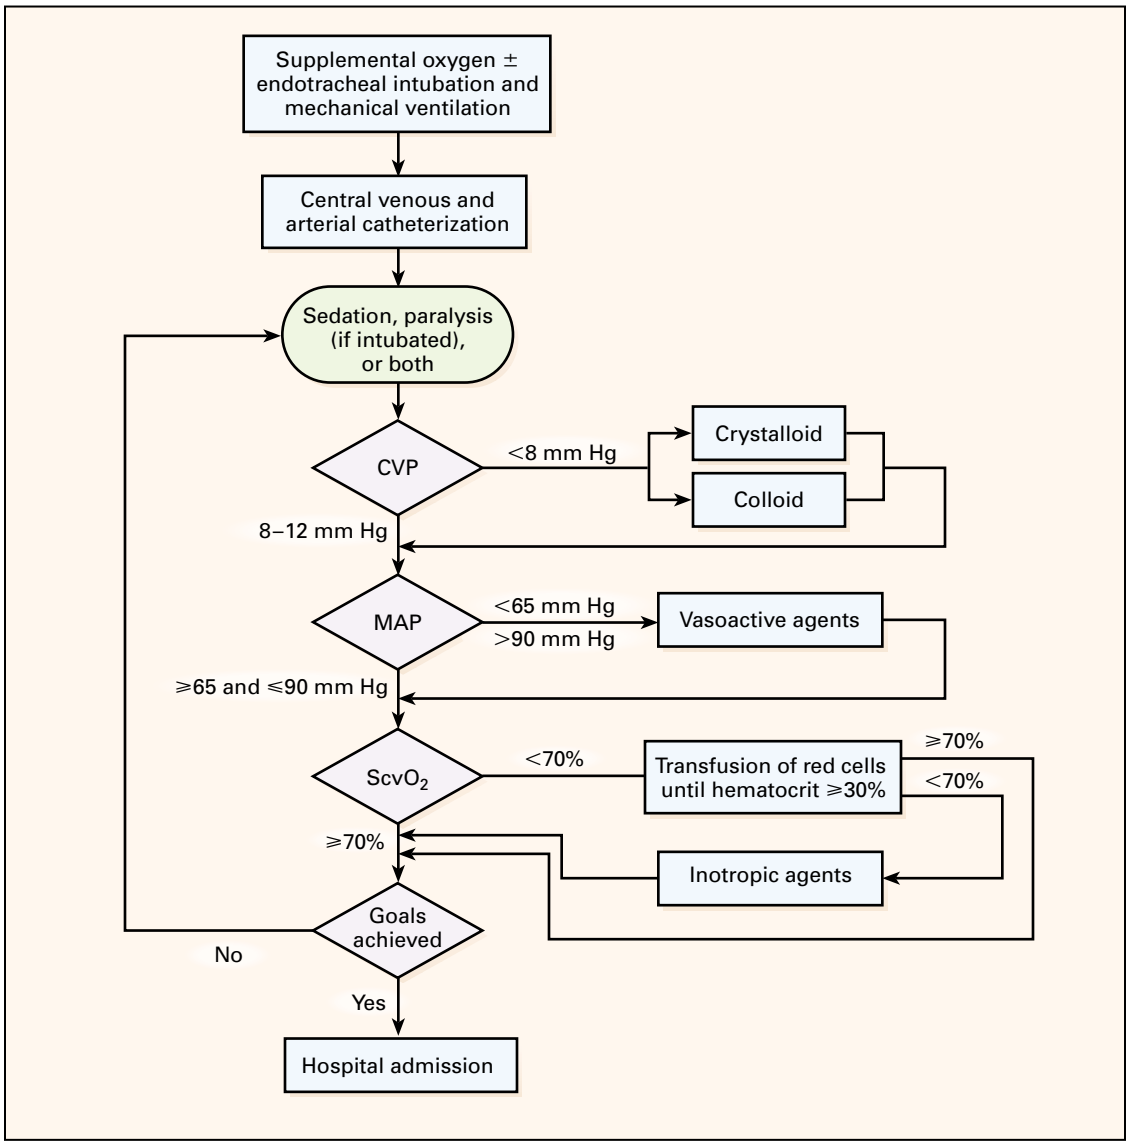

Figure 2. Protocol for Early Goal-Directed Therapy.
CVP denotes central venous pressure, MAP mean arterial pressure, and $ScvO_2$ central venous oxygen saturation.

All 263 were included in the intention-to-treat analyses. The patients assigned to standard therapy stayed a significantly shorter time in the emergency department than those assigned to early goal-directed therapy (mean [±SD], 6.3±3.2 vs. 8.0±2.1 hours; $P<0.001$). There was no significant difference between the groups in any of the base-line characteristics, including the adequacy and duration of antibiotic therapy (Table 1). Vital signs, resuscitation end points, organ-dysfunction scores, and coagulation-related variables were also similar in the two study groups at base line (Table 2).

Twenty-seven patients did not complete the initial six-hour study period (14 assigned to standard therapy and 13 assigned to early goal-directed therapy), for the following reasons: discontinuation of aggressive medical treatment (in 5 patients in each group), discontinuation of aggressive surgical treatment (in 2 patients in each group), a need for immediate surgery (in 4 patients assigned to standard therapy and in 3 assigned to early goal-directed therapy), a need for interventional urologic, cardiologic, or angiographic procedures (in 2 patients in each group), and refusal to continue participation (in 1 patient in each group) ($P=0.99$ for all comparisons). There were no significant differences between the patients who completed

‡For the period from 7 to 72 hours, the adjusted mean value was obtained from a mixed model.

the initial six-hour study period and those who did not in any of the base-line characteristics or base-line vital signs, resuscitation end points, organ-dysfunction scores, or coagulation-related variables (data not shown).

Vital Signs and Resuscitation End Points

During the initial six hours after the start of therapy, there was no significant difference between the two study groups in the mean heart rate (P=0.25) or central venous pressure (P=0.22) (Table 2). During this period, the mean arterial pressure was significantly lower in the group assigned to standard therapy than in the group assigned to early goal-directed therapy (P<0.001), but in both groups the goal of 65 mm Hg or higher was met by all the patients. The goal of 70 percent or higher for central venous oxygen saturation was met by 60.2 percent of the patients in the standard-therapy group, as compared with 94.9 percent of those in the early-therapy group (P<0.001). The combined hemodynamic goals for central venous pressure, mean arterial pressure, and urine output (with adjustment for patients with end-stage renal failure) were achieved in 86.1 percent of the standard-therapy group, as compared with 99.2 percent of the early-therapy group (P<0.001). During this period, the patients assigned to standard therapy had a significantly lower central venous oxygen saturation (P<0.001) and a greater base deficit (P=0.006) than those assigned to early goal-directed therapy; the two

groups had similar lactate concentrations (P=0.62) and similar pH values (P=0.26).

During the period from 7 to 72 hours after the start of treatment, the patients assigned to standard therapy had a significantly higher heart rate (P=0.04) and a significantly lower mean arterial pressure (P< 0.001) than the patients assigned to early goal-directed therapy; the two groups had a similar central venous pressure (P=0.68). During this period, those assigned to standard therapy also had a significantly lower central venous oxygen saturation than those assigned to early goal-directed therapy (P<0.001), as well as a higher lactate concentration (P=0.02), a greater base deficit (P<0.001), and a lower pH (P<0.001).

Organ Dysfunction and Coagulation Variables

During the period from 7 to 72 hours, the APACHE II score, SAPS II, and MODS were significantly higher in the patients assigned to standard therapy than in the patients assigned to early goal-directed therapy (P<0.001 for all comparisons) (Table 2). During this period, the prothrombin time was significantly greater in the patients assigned to standard therapy than in those assigned to early goal-directed therapy (P=0.001), as was the concentration of fibrin-split products (P<0.001) and the concentration of D-dimer (P=0.006). The two groups had a similar partial-thromboplastin time (P=0.06), fibrinogen concentration (P=0.21), and platelet count (P=0.51) (Table 2).

Mortality

In-hospital mortality rates were significantly higher in the standard-therapy group than in the early-therapy group (P=0.009), as was the mortality at 28 days (P=0.01) and 60 days (P=0.03) (Table 3). The difference between the groups in mortality at 60 days primarily reflected the difference in in-hospital mortality. Similar results were obtained after data from the 27 patients who did not complete the initial six-hour study period were excluded from the analysis (data not shown). The rate of in-hospital death due to sudden cardiovascular collapse was significantly higher in the standard-therapy group than in the early-therapy group (P=0.02); the rate of death due to multiorgan failure was similar in the two groups (P=0.27).

Administered Treatments

During the initial six hours, the patients assigned to early goal-directed therapy received significantly more fluid than those assigned to standard therapy (P<0.001) and more frequently received red-cell transfusion (P<0.001) and inotropic support (P<0.001), whereas similar proportions of patients in the two groups required vasopressors (P=0.62) and mechanical ventilation (P=0.90) (Table 4). During the period from 7 to 72 hours, however, the patients assigned to standard therapy received significantly more fluid than those assigned to early goal-directed therapy (P=0.01) and more often received red-cell transfusion (P< 0.001) and vasopressors (P=0.03) and underwent mechanical ventilation (P<0.001) and pulmonary-artery catheterization (P=0.04); the rate of use of inotropic agents was similar in the two groups (P=0.14) (Table 4). During the overall period from base line to 72 hours after the start of treatment, there was no significant difference between the two groups in the total volume of fluid administered (P=0.73) or the rate of use of inotropic agents (P=0.15), although a greater proportion of the patients assigned to standard therapy than of those assigned to early goal-direct-

P value	0.12	0.04	0.01

*Plus–minus values are means ±SD. Because some patients received a specific treatment both during the period from 0 to 6 hours and during the period from 7 to 72 hours, the cumulative totals for those two periods do not necessarily equal the values for the period from 0 to 72 hours. EGDT denotes early goal-directed therapy.

†Administered vasopressors included norepinephrine, epinephrine, dopamine, and phenylephrine hydrochloride.

‡All pulmonary-artery catheters were inserted while patients were in the intensive care unit.

ed therapy received vasopressors (P=0.02) and mechanical ventilation (P=0.02) and underwent pulmonary-artery catheterization (P=0.01), and a smaller proportion required red-cell transfusion (P<0.001). Though similar between the groups at base line (P=0.91), the mean hematocrit during this 72-hour period was significantly lower in the standard-therapy group than in the early-therapy group (P<0.001). Despite the transfusion of red cells, it was significantly lower than the value obtained at base line in each group (P<0.001 for both comparisons) (Table 2).

Consumption of Health Care Resources

There were no significant differences between the two groups in the mean duration of vasopressor therapy (2.4±4.2 vs. 1.9±3.1 days, P=0.49), the mean duration of mechanical ventilation (9.0±13.1 vs. 9.0±11.4 days, P=0.38), or the mean length of stay in the hospital (13.0±13.7 vs. 13.2±13.8 days, P=0.54). However, of the patients who survived to hospital discharge, those assigned to standard therapy had stayed a significantly longer time in the hospital than those assigned to early goal-directed therapy (18.4±15.0 vs. 14.6±14.5 days, P=0.04).

DISCUSSION

Severe sepsis and septic shock are common and are associated with substantial mortality and substantial consumption of health care resources. There are an estimated 751,000 cases (3.0 cases per 1000 population) of sepsis or septic shock in the United States each year, and they are responsible for as many deaths each year as acute myocardial infarction (215,000, or 9.3 percent of all deaths).[29] In elderly persons, the incidence of sepsis or septic shock and the related mortality rates are substantially higher than those in younger persons. The projected growth of the elderly population in the United States will contribute to an increase in incidence of 1.5 percent per year, yielding an estimated 934,000 and 1,110,000 cases by the years 2010 and 2020, respectively.[29] The present annual cost of this disease is estimated to be $16.7 billion.[29]

The transition from the systemic inflammatory response syndrome to severe sepsis and septic shock involves a myriad of pathogenic changes, including circulatory abnormalities that result in global tissue hypoxia.[1,2] These pathogenic changes have been the therapeutic target of previous outcome studies.[12] Although this transition occurs over time, both out of the hospital and in the hospital, in outcome studies interventions have usually been initiated after admission to the intensive care unit.[12] In studies of goal-directed hemodynamic optimization, in particular, there was no benefit in terms of outcome with respect to normal and supranormal hemodynamic end points, as well as those guided by mixed venous oxygen saturation.[9,13] In contrast, even though we enrolled patients with lower central venous oxygen saturation and lower central venous pressure than those studied by Gattinoni et al.[9] and with a higher lactate concentration than those studied by Hayes et al.,[13] we found significant benefits with respect to outcome when goal-directed therapy was applied at an earlier stage of disease. In patients with septic shock, for example, Hayes et al. observed a higher in-hospital mortality rate with aggressive hemodynamic optimization in the intensive care unit (71 percent) than with control therapy (52 percent), whereas we observed a lower mortality rate in patients with septic shock assigned to early goal-directed therapy (42.3 percent) than in those assigned to standard therapy (56.8 percent).

The benefits of early goal-directed therapy in terms of outcome are multifactorial. The incidence of death due to sudden cardiovascular collapse in the standard-therapy group was approximately double that in the group assigned to early goal-directed therapy, suggesting that an abrupt transition to severe disease is an important cause of early death. The early identification

of patients with insidious illness (global tissue hypoxia accompanied by stable vital signs) makes possible the early implementation of goal-directed therapy. If sudden cardiovascular collapse can be prevented, the subsequent need for vasopressors, mechanical ventilation, and pulmonary-artery catheterization (and their associated risks) diminishes. In addition to being a stimulus of the systemic inflammatory response syndrome, global tissue hypoxia independently contributes to endothelial activation and disruption of the homeostatic balance among coagulation, vascular permeability, and vascular tone.[30] These are key mechanisms leading to microcirculatory failure, refractory tissue hypoxia, and organ dysfunction.[2,30] When early therapy is not comprehensive, the progression to severe disease may be well under way at the time of admission to the intensive care unit.[16] Aggressive hemodynamic optimization and other therapy[12] undertaken thereafter may be incompletely effective or even deleterious.[13]

The value of measurements of venous oxygen saturation at the right atrium or superior vena cava (central venous oxygen saturation) instead of at the pulmonary artery (mixed venous oxygen saturation) has been debated,[31] in particular, when saturation values are above 65 percent. In patients in the intensive care unit who have hyperdynamic septic shock, the mixed venous oxygen saturation is rarely below 65 percent.[32] In contrast, our patients were examined during the phase of resuscitation in which the delivery of supplemental oxygen is required (characterized by a decreased mixed venous oxygen saturation and an increased lactate concentration), when the central venous oxygen saturation generally exceeds the mixed venous oxygen saturation.[33,34] The initial central venous oxygen saturation was less than 50 percent in both study groups. The mixed venous oxygen saturation is estimated to be 5 to 13 percent lower in the pulmonary artery[33] and 15 percent lower in the splanchnic bed.[35] Though not numerically equivalent, these ranges of values are pathologically equivalent and are associated with high mortality.[32,36] Among all the patients in the current study in whom the goals with respect to central venous pressure, mean arterial pressure, and urine output during the first six hours were met, 39.8 percent of those assigned to standard therapy were still in this oxygen-dependent phase of resuscitation at six hours, as compared with 5.1 percent of those assigned to early goal-directed therapy. The combined 56.5 percent in-hospital mortality of this 39.8 percent of patients, who were at high risk for hemodynamic compromise, is consistent with the results of previous studies in the intensive care unit.[32,36]

In an open, randomized, partially blinded trial, there are unavoidable interactions during the initial period of the study. As the study progressed, the patients in the standard-therapy group may have received some form of goal-directed therapy, reducing the treatment effect. This reduction may have been offset by the slight but inherent bias resulting from the direct influence of the investigators on the care of the patients in the treatment group. The potential period of bias was 9.9±19.5 percent of the overall hospital stay in the standard-therapy group and 7.2±12.0 percent of that in the group assigned to early goal-directed therapy ($P=0.20$). This interval was minimal in comparison with those in previous studies[9,13] because the clinicians who assumed responsibility for the remainder of hospitalization were completely blinded to the randomization order.

We conclude that goal-directed therapy provided at the earliest stages of severe sepsis and septic shock, though accounting for only a brief period in comparison with the overall hospital stay, has significant short-term and long-term benefits. These benefits arise from the early identification of patients at high risk for cardiovascular collapse and from early therapeutic intervention to restore a balance between oxygen delivery and oxygen demand. In the future, investigators conducting outcome trials in patients with sepsis should consider the quality and timing of the resuscitation before enrollment as an important outcome variable.

Supported by the Henry Ford Health Systems Fund for Research, a Weatherby Healthcare Resuscitation Fellowship, Edwards Lifesciences (which provided oximetry equipment and catheters), and Nova Biomedical (which provided equipment for laboratory assays).

We are indebted to the nurses, residents, senior staff attending physicians, pharmacists, patient advocates, technicians, and billing and administrative personnel of the Department of Emergency Medicine; to the nurses and technicians of the medical and surgical intensive care units; and to the staff members of the Department of Respiratory Therapy, Department of Pathology, Department of Medical Records, and Department of Admitting and Discharge for their patience and their cooperation in making this study possible.

40 months. Even though no cases of hyperplasia were identified, only 101 of the 150 participants (67%) underwent endometrial biopsy at the end of the treatment. Even a few cases of hyperplasia in the women who did not undergo biopsy would alter the findings. Although there are distinct advantages of levonorgestrel-containing IUDs, including contraception in perimenopausal women and consistent delivery of progestin for up to 5 years, the lack of robust data on safety and the fact that the use of IUDs requires a procedure for placement and for removal limit their role in postmenopausal hormone therapy.

Management of Sepsis

TO THE EDITOR: The review by Russell (Oct. 19 issue)[1] recommends the protocol used by Rivers et al.[2] and adopted in the Surviving Sepsis Campaign guidelines[3] for the initial resuscitation in severe sepsis. Although others[4] have warned against the use of this protocol, this warning did not receive the attention we think it deserves. Estimates of intravascular volume based on any given level of filling pressure do not reliably predict the response to fluid administration. In addition, patients with sepsis have characteristically high central venous oxygen saturation because of decreased oxygen extraction. The initial mean central venous oxygen saturation of 50% in the study by Rivers et al. and the high mortality rate raise the possibility that these patients arrived at the hospital in a state of late, untreated, hypovolemic sepsis.[5,6] This may be due in part to reduced access to health care and in part to the cost of care.[5] We believe that the hemodynamic component of these guidelines cannot, at this time, be applied to all patients with sepsis, particularly those in whom sepsis develops while they are in the hospital. Both physiologically and clinically this protocol may be wrong for many patients with sepsis.

TO THE EDITOR: Two points in the article by Russell warrant further discussion. First, in the discussion of early, goal-directed therapy, the author recommends maintaining a central venous pressure of 8 to 12 mm Hg. Surviving Sepsis Campaign guidelines recommend the same central venous pressure but add that in mechanically ventilated patients a higher target central venous pressure, 12 to 15 mm Hg, is recommended to account for the increased intrathoracic pressure.[1] Second, in the discussion about activated protein C, there is one important observation that Russell does not mention. In the Administration of Drotrecogin Alfa (Activated) in Early Stage Severe Sepsis (ADDRESS) trial,[2] post hoc analysis of the subgroup of patients who had undergone recent surgery (within the previous 30 days) indicated that surgical patients with single-organ dysfunction who received activated protein C had a higher 28-day mortality than the placebo group (20.7% vs. 14.1%, P=0.03). This particular finding triggered a retrospective analysis of the same

subgroup in the Recombinant Human Activated Protein C Worldwide Evaluation in Severe Sepsis (PROWESS) study, and a similar effect was noted.[3] This outcome clearly argues against the use of activated protein C in this subgroup of patients.

3. Bernard GR, Vincent JL, Laterre PF, et al. Efficacy and safety of recombinant human activated protein C for severe sepsis. N Engl J Med 2001;344:699-709.

TO THE EDITOR: I wish that Russell's review had included a more comprehensive discussion of the role of recombinant human activated protein C. His coverage of the ADDRESS trial results excludes the disturbing data on the subgroups of patients with multiple-organ failure and those with an Acute Physiology and Chronic Health Evaluation (APACHE II) score greater than 24 (approved uses): no treatment benefit was shown, and the 28-day mortality rate was even higher with activated protein C than with placebo.[1-3] In contrast, favorable data on high-risk subgroups in the PROWESS trial are highlighted. The high overall rate of serious bleeding reported in the Extended Evaluation of Recombinant Human Activated Protein C (ENHANCE) trial also deserved comment, in my estimation.[1]

Russell suggests that activated protein C may be useful in the emergency care of patients with sepsis, yet doubts regarding any role for activated protein C have been expressed. Additional concerns have arisen from the PROWESS trial: important differences between study groups in the severity of disease at baseline, especially in higher-risk subgroups[2,3]; inadequate blinding; differences in the rates of do-not-resuscitate orders; the lack of reduced mortality rates at 28 days among patients without severe, long-term illness; disappointing data on discharging patients to home[4]; and the distinct possibility that meeting the criteria for stopping the trial early occurred by chance.[3]

TO THE EDITOR: The review by Russell states that our randomized, controlled trials investigating the effect of intensive versus conventional insulin therapy in patients in the surgical intensive care unit (ICU) (1548 patients) and the medical ICU (1200 patients) did not include patients with sepsis.[1,2] However, among the mixed medical and surgical populations in these randomized, controlled trials, 950 patients could be identified as having sepsis at the time of admission to the ICU.[3,4] We report here the effect of intensive insulin therapy in the patients with sepsis as compared with the effect in 1798 other patients (Table 1).

Despite a higher incidence of hypoglycemia among patients with sepsis than among those without sepsis (intensive insulin therapy, 20% vs. 7%; $P<0.001$; conventional insulin therapy, 3% vs. 1%; $P=0.02$), the effect of intensive insulin therapy on the outcome for patients with sepsis was similar to the effect on the outcome for other patients. This post hoc analysis lacked the statistical power to prove that the observed 4% absolute reduction in mortality was significant in an intention-to-treat analysis (this would require 2200 patients per group). However, the 8% absolute reduction in mortality and the 21% reduction in critical illness polyneuropathy among patients with sepsis and long stays in the ICU who were treated with intensive insulin therapy were significant, and the analysis did not reveal harm to

* Plus–minus values are means ±SD. Percentages may not total 100 because of rounding. APACHE denotes Acute Physiology and Chronic Health Evaluation, and CI confidence interval.
† Sepsis was defined according to modified Bone criteria[4] as suspected or documented infection on the day of admission to the ICU and fulfillment of at least two of the three criteria for the system inflammatory response syndrome for which data were available (i.e., receiving ventilatory support, white-cell count ≤4000 or ≥12,000 per cubic millimeter, and body temperature ≤36°C or ≥38°C). Patients who had had cardiac surgery or trauma were excluded for this definition.
‡ The body-mass index is the weight in kilograms divided by the square of the height in meters.
§ Among the patients with sepsis, data on blood glucose levels were not available for three patients receiving conventional insulin therapy and four patients receiving intensive insulin therapy. For other patients, such data were not available for three patients receiving conventional insulin therapy and six patients receiving intensive insulin therapy.
¶ Critical illness polyneuropathy was diagnosed with the use of electromyography by an investigator who was unaware of the patients' treatment status. Data are for patients who were screened (i.e., those who were in the ICU ≥7 days).
‖ The P value is for the comparison of patients who had hypoglycemia with those who did not.

patients treated with intensive insulin therapy for less than 3 days.

THE AUTHOR REPLIES: Perel and Segal suggest that filling pressures do not reliably predict the response to fluid. Central venous oxygen saturation was very low in the study by Rivers et al.[1];

thus, they studied late, untreated hypovolemic sepsis. Relationships among central venous oxygen saturation, intravascular volume, fluid therapy, and outcomes are complex. The study by Rivers et al. is the only adequately powered trial of early, goal-directed therapy; unfortunately, there are no similar trials regarding inpatients with sepsis. Although other investigators have found higher initial central venous oxygen saturation in patients with sepsis in the emergency setting[2] than did Rivers et al., additional studies are needed to describe the range of baseline values for central venous oxygen saturation in such patients.

Khurana and Vinayek suggest that ventilated patients require higher central venous pressure because of increased intrathoracic pressure; I agree. The study by Rivers et al.[1] suggests that the response of the central venous pressure (and central venous oxygen saturation) to fluid challenge may be helpful in assessing fluid resuscitation. I agree that surgical patients who have single-organ dysfunction are at increased risk for death when they are treated with activated protein C and therefore should not receive this treatment.

Mackenzie and Bartelink note that there was "no treatment benefit . . . and the 28-day mortality rate was even higher with activated protein C than with placebo" in a subgroup of high-risk patients in the ADDRESS study.[3] The APACHE II high-risk subgroup of the ADDRESS trial was small (324 patients), and the power was only 0.63 (to refute the mortality results in the PROWESS trial in high-risk patients absolutely); thus, it is difficult to determine statistically whether the subgroup result in the ADDRESS trial is a true negative result. The bleeding rates in the ENHANCE trial are difficult to assess because there was no concurrent control group; however, I would reemphasize the need for careful assessment and monitoring of patients treated with activated protein C. Mackenzie and Bartelink raise concerns regarding the PROWESS trial (my responses are in parentheses), such as baseline characteristics (overall, they were balanced; also see Ely et al.[4]), inadequate blinding (difficult to assess without data about outcomes), do-not-resuscitate rates (difficult to compare with other studies, since do-not-resuscitate orders are underreported), chronic illness (post hoc subgroup analysis with inadequate power), disappointing rates of discharge to home (overall discharge rate was significantly higher [$P=0.03$][5] with activated protein C, especially in the high-risk APACHE II subgroup), and early stopping by chance (the overall P value of 0.005 suggests a 5 in 1000 chance of a false positive result).

I thank Van Cromphaut and colleagues for reporting on subgroups of patients with sepsis from their trials of intensive insulin therapy.[6,7] They argue that intensive insulin therapy decreased mortality among patients with sepsis who had a long stay in the ICU (≥3 days). This post hoc subgroup analysis is hypothesis generating and indicates the need for a trial that examines the association between the duration of the ICU stay and intensive insulin therapy in patients with sepsis.

Before the publication of my article, I informed the *Journal* that I had received grant support from Eli Lilly, Chiron, and Glaxo. This information was inadvertently omitted from the article.
